episodes in all patients who received treatment (Chinegwundoh and Anie, 2004). However, in more than 50% of patients (5 of 9) priapism recurred after treatment cessation. Similar results have been described by others in case reports (Gbadoe et al, 2002; Shamloul and el Nashaar, 2005). Long-term estrogen therapy is not recommended because of the potential cardiovascular side effects. **GnRH analogues**, goserelin acetate and leuprolide acetate, have been described in case reports (Levine and Guss, 1993; Shamloul and el Nashaar, 2005). Chronic therapy with GnRH analogues in combination with penile injection of α -adrenergics as needed has been reported in the management of ischemic stuttering priapism (Steinberg and Eyre, 1995). Discontinuation of GnRH analogues typically leads to stuttering resumption. **Antiandrogens** including flutamide, bicalutamide, and chlormadinone have been used to interrupt stuttering priapism, and their use has been detailed in case reports. Antiandrogens may have benefit to patients over the GnRH analogues because they are orally administered and because some patients continue having sexually stimulated erections (Costabile, 1998; Dahm et al, 2002; Yamashita et al, 2004). **Abern and Levine (2009)** used nightly administration of the antifungal agent **oral ketoconazole** and **prednisone** to suppress nocturnal erections as a preventive strategy for recurrent ischemic priapism in 8 patients followed for 1.5 years. The protocol required titrating dosages and monitoring of nocturnal erections and serum testosterone levels; mean testosterone levels fell from a baseline of 475 ng/dL to 275 ng/dL. The fall in testosterone levels appeared to be a surrogate for efficacy in preventing significant episodes of priapism. Ketoconazole inhibits steroidogenesis in the adrenal and gonadal tissues; it has a half-life of 8 hours. Ketoconazole inhibits cortisol production, necessitating concomitant prednisone administration. In the Abern and Levine protocol, men with recurring ischemic priapism were treated with ketoconazole 200 mg given orally (PO) every 8 hours and prednisone 5 mg at bedtime for 2 weeks, followed by ketoconazole nightly without prednisone supplementation. **Rachid-Filho and colleagues (2009)** have described the efficacy of oral **5 α -reductase inhibitors** (finasteride) in the management of sickle cell stuttering priapism. They administered finasteride to 35 patients over 120 days in doses that decreased monthly from 5 mg/day to 3 mg/day and then 1 mg/day in the final month. This was not a controlled trial, but careful observation of stuttering episodes was made. They found at the beginning of treatment that the mean number of episodes of stuttering priapism per patient was 22.7, and at the end of 4 months the mean number of episodes per patient was 2.1. The optimal effects were found at 5- and 3-mg daily doses. Six of 35 patients in this study developed painless gynecomastia. Finasteride is a 5 α -reductase inhibitor approved in the United States for management of symptomatic BPH (Proscar 5 mg) and male pattern alopecia (Propecia 1 mg); finasteride and dutasteride are type II 5 α -reductase inhibitors. This class of drugs reduces conversion of testosterone to dihydrotestosterone, which is believed to be many times more potent at the cellular level. Paradoxically, when measured during clinical trials, serum testosterone levels go up in healthy controls and patients administered finasteride or dutasteride. Neither drug is approved for use in patients with stuttering ischemic priapism.

Baclofen

Studies in both rats and humans suggest that baclofen inhibits penile erection and ejaculation, through γ -aminobutyric acid (GABA) receptor activity. In rats, stimulation of GABA_B receptors in the lumbosacral spinal cord inhibits erection (Bitran et al, 1988; Paredes and Agmo, 1995; Vaidyanathan et al, 2004). **Denys and colleagues (1998)** reported on nine men with multiple sclerosis or spinal cord injuries who were treated for 44 months with intrathecal baclofen for muscle spasticity; eight of nine reported decreased erectile function, which reversed on cessation of baclofen. **Rourke and colleagues (2002)** first reported on the use of oral nightly baclofen 40 mg in the management of recurrent priapism in patients with neurologic lesions. **D'Aleo and colleagues (2009)** were the first to report on the use of an intrathecal pump to administer baclofen

180 μ g daily for the management of skeletal muscle spasm and recurrent priapism in a patient with spinal cord injury; the patient was refractory to treatment with oral administration of 75 mg/day but responded to a test dose of 25 μ g intrathecally. The neurologic literature generally fails to categorize these erectile events as ischemic or nonischemic. Triggering events may be tactile nonsexual stimulation causing repeated reflexogenic erections. Better characterization of these unwanted erections in men with upper motor neural lesions is necessary to appreciate hemodynamics, inciting events, duration, and impact on erectile function. There have been reports to the FDA that men with baclofen infusion pumps experience a withdrawal syndrome when those pumps fail. The withdrawal syndrome has been characterized by return of spasticity, agitation, sleeplessness, and priapism. Advanced symptoms resemble autonomic dysreflexia and may include rhabdomyolysis. The syndrome responds to oral baclofen dosing until intrathecal therapy can be resumed. In non-neurogenic patients, daily administration of baclofen is associated with drowsiness, nausea, complaints of fatigue, and ED. Recurrent reflexogenic erections are clearly an unwanted condition associated with muscle spasticity in men with spinal cord lesions and neurologic disease, but it remains to be demonstrated whether the duration and hemodynamics of such erectile events are similar to ischemic stuttering priapism typical in SCD.

Phosphodiesterase Type 5 Inhibitors in the Management of Stuttering Priapism: A Counterintuitive Treatment Strategy

Bialecki and Bridges (2002) first reported on sildenafil having a paradoxical effect in controlling stuttering priapism in three patients with SCD. Although this proposal would immediately seem illogical on the basis of the understanding that PDE5 inhibitors exert erectogenic effects, there is a scientific basis for using these agents to treat priapism.

In a small case series, Burnett and colleagues showed that daily sildenafil or tadalafil therapy reduces ischemic priapism episodes in men with stuttering priapism (Burnett et al, 2006a). When used in long-term regimens unassociated with erection stimulatory conditions, PDE5 inhibitor therapy alleviates recurrent priapism episodes in men with SCD-associated priapism without affecting normal erectile capacity (Burnett et al, 2006b; Bivalacqua et al, 2009a). The working theory is that surges of cGMP go unchecked because of downregulated levels of PDE5; this results in stimuli such as nocturnal erection, which causes unchecked corporal smooth muscle relaxation. In initial series, the short-acting PDE5 inhibitor sildenafil citrate was given at a dose of 25 mg oral daily, with escalation to 50 mg daily. Subsequently these investigators reported on tadalafil at a dose of 5 or 10 mg taken orally three times weekly. Multicenter, randomized, double-blind, placebo-controlled clinical trials are underway. PDE5 inhibitors should be started under conditions of complete penile flaccidity, not during a stuttering episode. Efficacy is seen after a week or more of administration.

SURGICAL MANAGEMENT OF ISCHEMIC PRIAPISM

Surgical management of ischemic priapism is indicated after repeated penile aspirations and injections of sympathomimetics have failed or if such an attempt has resulted in a significant cardiovascular side effect. At present there is a paucity of data regarding the timing of surgical intervention following initiation of medical treatment, although the 2004 International Consultation on Sexual Medicine in Paris recommended corporal aspiration and α -adrenergic agonists for at least 1 hour before consideration of shunting (Pryor et al, 2004). Early surgical intervention may be preferable in patients with malignant or poorly controlled hypertension or for men who are using monoamine oxidase inhibitor medications contraindicating α -adrenergic therapies. A comprehensive discussion and documentation that includes baseline erectile function, duration of priapism, risks and benefits

KEY POINTS: MEDICAL MANAGEMENT OF STUTTERING PRIAPISM

- The goals of managing a patient with stuttering priapism include prevention of future episodes, preservation of erectile function, and balancing the risks versus benefits of various treatment options.
- A trial of daily oral α -adrenergic therapy may be used in the management of patients (adults and children) with stuttering priapism associated with hemoglobinopathies. Efficacy should be monitored through frequency and duration of stuttering episodes, blood pressure, and normal erectile capacity.
- A trial of daily oral PDE5 inhibitor therapy may be used in the management of patients (adults and children) with stuttering priapism associated with hemoglobinopathies. Treatment should be initiated under conditions of complete penile flaccidity. Efficacy should be monitored through frequency and severity of stuttering episodes, as well as PDE5 inhibitor side effects and normal erectile capacity.
- A trial of GnRH agonists or antiandrogens may be used in the management of adult patients with stuttering priapism. Hormonal agents should not be used in patients who have not achieved full sexual maturation and adult stature. Chronic GnRH or antiandrogen administration in men may affect libido or fertility, cause gynecomastia, cause hot flashes, promote osteoporosis, increase the risks of cardiovascular disease, and worsen sexual function.
- When administered at home for prolonged morning erections, an injection of an intracavernous α -adrenergic agent may avert a full-blown episode of ischemic priapism. ICI of phenylephrine (by the adult patient or parent) should be considered as an adjunct to daily systemic therapies in patients with stuttering priapism.

of the surgery, and ED should be held with the patient or guardian and an informed consent form signed by the patient or guardian.

Shunting

It is generally accepted that the longer an episode of ischemic priapism lasts, the greater the likelihood of compromised erectile function in the future. Early reviews concluded that priapism lasting longer than 24 hours was associated with a 90% ED rate (Pryor and Hehir, 1982). Kulmala and colleagues (1996) reported 92% erectile function preservation among patients with ischemic priapism reversed in less than 24 hours, but only 22% preservation of erectile function among men with priapism lasting longer than 7 days. Recommendations based on well-documented erectile function outcomes are few. One recent study does document erectile function outcomes by contemporary standards (International Index of Erectile Function [IIEF]). Bennett and Mulhall (2008) carefully documented 39 patients with SCD priapism who came to their emergency department over 8 years; men were routinely interviewed for erectile function status within 4 weeks of priapism and interventions. Of the 39 African-American men followed, 73% acknowledged prior episodes of stuttering; 85% had previously been diagnosed with SCD; but only 5% had been counseled in SCD clinics or were aware that priapism was a complication of SCD. A standard protocol of aspiration and phenylephrine injection was performed; shunting for failure of medical management was performed in 28%. In patients in whom priapism was reversed, spontaneous erections (with or without use of sildenafil) were reported in 100% of men when priapism was reversed by 12 hours; 78% when reversed by 12 to 24 hours; and 44% when reversed by 24 to 36 hours. In this contemporary series of SCD patients, no men reported the return of spontaneous erections after priapism lasting 36 hours or more. The International Society for Sexual Medicine

Standards Committee (expert opinion) stated that shunting is to be considered for ischemic priapism events lasting 72 hours or less. Consideration should be given to foregoing a shunt in priapism events lasting longer, in particular when cavernous thrombosis is evident and no blood can be aspirated from the corporal bodies (Pryor et al, 2004; Mulhall, 2006).

The objective of shunt surgery is reoxygenation of the cavernous smooth muscle. The shared principle of shunt procedures is to reestablish corporal inflow by relieving venous outflow obstruction; this requires creation of a fistula between the CC and glans penis, CC and corpus spongiosum, or CC and dorsal or saphenous veins. Shunt procedures are subdivided on the basis of anatomic location on the penis (Lue and Pescatori, 2006) (Fig. 28-8).

- Percutaneous distal shunts—Ebbehoj (1974), Winter (1976), or T shunt (Brant et al, 2009)
- Open distal shunt—Al-Ghorab (Hanafy et al, 1976; Borrelli et al, 1983) or corporal snake (Burnett and Pierorazio, 2009)
- Combined T shunt and corporal snake maneuver—Zacharakis and colleagues (2014b)
- Open proximal shunt—Quackles (1964) or Sacher and colleagues (1972)
- Saphenous vein—Grayhack and colleagues (1964)
- Deep dorsal vein shunt—Barry (1976)

A distal cavernoglanular shunt should be the first choice of shunting procedures because it is technically easier to perform than proximal shunting. Percutaneous distal shunting is less invasive than open distal shunting and can be performed with local anesthetic in the emergency department. The most recently described distal shunt (Brant et al, 2009) creates a T-shaped shunt between the CC and glans penis. Brant and associates (2009) describes 13 men with priapism durations longer than 24 hours (in 6 of 13, other distal or proximal shunt procedures had failed). All T shunts were performed after penile anesthetic block; in 12 of 13 patients, the priapism was successfully reversed by initial intervention. In T shunting a No. 10 blade is placed vertically through the glans 4 mm away from the meatus; the blade pierces through the glans to the CC and is rotated 90 degrees away from the urethra and removed (Fig. 28-9). Deoxygenated blood is milked out of the wound. The glans is then sutured with absorbable suture. The authors recommend discharge home if the penis remains flaccid for 15 minutes (Brant et al, 2009). If erection returns or persists, a second T shunt is recommended on the opposite side of the meatus. When ischemic priapism has been present for more than 36 hours, immediate placement of bilateral T shunts is recommended, with passage of 20-Fr dilators into the fistula tract and well into the CC down to the crus. This technique is more traumatic and will require general anesthesia. Burnett and Pierorazio (2009) have described a similar technique to resolve ischemic priapism refractory to first-line interventions. Their procedure, known as the *corporal snake*, is a modification of the Al-Ghorab corporoglanular shunt (see Fig. 28-8B and Fig. 28-10). With the patient under general anesthesia, a 2-cm transverse incision is made on the glans; the distal tips of the rigid CC are incised and grasped with 2-0 stay sutures or Kocher clamps. Deoxygenated blood is milked out of the CC, but rather than excising a wedge of tunica and underlying CC muscle, a 7/8 Hegar dilator is advanced through each of the tunica windows proximally several centimeters to release blood and thrombus. The penis is made flaccid by repeated manual compression and release; the glans skin is then approximated with 4-0 chromic sutures; a urethral catheter is placed, and lightly compressive dressing is applied to the genitalia.

Segal and associates (2013) retrospectively reviewed the Johns Hopkins Hospital experience with the corporal snake maneuver. Ten patients with ischemic priapism with a mean duration of 75 hours (range 24 to 288 hours) refractory to medical intervention and simple distal shunting (Winter or Ebbehøj) were treated surgically with the corporal snake maneuver; in 8 the priapism resolved, and they had no postoperative recurrence during 6-month follow-up. In 2 patients the priapism did not respond; they were treated by insertion of inflatable penile implant at time of presentation. Complication rates were significant (20%); complications

Figure 28-8. A, Winter shunt. The distal cavernoglanular shunt procedure is depicted by the transglanular placement of a large-bore needle or angiocatheter in the distal glans and corpus cavernosum. B, Corporal snake maneuver is a modification of the Al-Ghorab shunt. After excision of a 5-mm circular core of distal tunica albuginea, a 7/8 Hegar dilator is inserted down each corporal body through the tunica window. (A, © Brady Urological Institute; B, from Burnett AL, Pierorazio PM. Corporal “snake” maneuver: corporoglanular shunt surgical modification for ischemic priapism *J Sex Med* 2009;6:1171–76.)

Figure 28-9. A, A No. 11 blade is used for an Ebbehoj percutaneous cavernoglanular shunt, and a No. 10 blade is used for a T shunt. B and C, Note the differences between the Ebbehoj and T shunts. In the Ebbehoj technique the No. 11 blade leaves a straight incision into the glans and corpus cavernosum. In the creation of a T shunt the No. 10 blade is rotated 90 degrees after insertion and is withdrawn. In both the percutaneous techniques deoxygenated blood is milked out of the open wounds; once bright red blood is seen, the skin is closed, leaving the deeper incision of the open fistula. In either procedure the maneuver may be repeated on the opposite corpus. (Courtesy Dr. Tom Lue.)

included wound infection, penile skin necrosis, and urethrocutaneous fistula. The authors documented sexual health function outcomes in these patients treated for refractory priapism lasting 24 to 288 hours; all had significant complaints of ED at 6 months, with 2 of 8 receiving subsequent penile implants (Segal et al, 2013). Zacharakis and colleagues (2014b) described the efficacy and outcomes of combining the T shunt (Brant et al, 2009) with the corporal snake maneuver in 45 patients. All were refractory to medical reversal of ischemic priapism. The combined distal surgical technique was successful in resolving the acute priapism if duration was less than 24 hours but had limited efficacy in cases of priapism exceeding 48 hours. Corporal needle biopsies were performed in

each patient and documented smooth muscle necrosis, worsening as a function of time and uniform in all men with more than 48 hours of ischemia. At 6 months, erectile function outcomes were assessed by the erectile function domain score from the IIEF-5. T shunt with corporal snake tunneling successfully reversed ischemic priapism in all patients with less than 24 hours' duration, but at 6 months ED was reported by 50% of men. The authors (Zacharakis et al, 2014b) conclude that the cutoff for reversing ischemic priapism in the hopes of preserving future erectile function is 48 hours. They advise that management of refractory ischemic priapism of longer than 48 hours' duration should include discussion of immediate insertion of a penile implant.

Figure 28-10. An open corporoglanular shunt is indicated if percutaneous shunting fails to reestablish cavernous blood inflow. The Al-Ghorab shunt requires the excision of circular cone segments of the distal tunica albuginea (5 × 5 mm). (By permission of Mayo Foundation for Medical Education and Research. The key factors determining successful surgical reversal of ischemic priapism are evacuation of thrombus, reestablishing cavernous inflow, and patency of shunt. Theoretically, larger open shunt procedures are likely to result in higher shunt patency rates; there are no data comparing percutaneous and open distal shunts. The surgeon must be guided by familiarity with various techniques: percutaneous shunting, open distal shunting, proximal shunting, and vein shunting. Although distal shunting can be performed with penile block and sedation in the emergency department, open shunting, especially that requiring passage of dilators into the CC, will likely require general anesthesia and an operating room suite. At the completion of the shunt, patency can be verified in the operating room and subsequently the recovery room in a number of ways: bright oxygenated blood should be seen emanating from the corporal bodies; intracavernous pressures should fall; the penis should detumescence and refill with sequential compression and release; and CDU should show resumption of cavernous artery inflow (Lue, 2002; Nixon et al, 2003; Chiou et al, 2009a) (Box 28-3). Complications of shunting include penile edema, hematoma, infection, urethral fistula, penile necrosis, and pulmonary embolism. Distal shunt failures may be the consequence of inadequate size and/or formation of a clot at the site. Distal shunt failure invariably leads to further surgical interventions. Shunts cut through the collagen-rich tunica albuginea; collagen-activated platelets and fibrin form as a reaction to surgical injury and will work to seal off

BOX 28-3 Assessing Corpora Cavernosa Shunt Patency

Visualization of bright red blood in corporal aspirate
Corporal blood gas
Color Doppler ultrasonography
Measurement of intracavernous pressure
Penile compression maneuver (squeeze and release)

Figure 28-11. The proximal open shunt technique to establish communication between the corpus spongiosum and corpus cavernosum was first described by Quackles in 1964. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

the shunt. Premature thrombosis of the site could lead to shunt failure. Three suggestions have been made to prevent shunt obstruction and subsequent failure: (1) compressive penile dressings should be avoided; (2) the patient should periodically squeeze and release the distal penis to “milk” the shunt maintaining patency; and (3) anticoagulation should be considered with shunting. The literature contains only one such recommendation for perioperative anticoagulation for the prevention of premature shunt obstruction in ischemic priapism. That regimen includes preoperative aspirin 325 mg coupled with subcutaneous heparin 5000 units and postoperative aspirin 81 mg daily for 2 weeks (Lue and Garcia, 2013).

The most commonly described proximal shunt is the unilateral shunt, described by Quackles in 1964 (Fig. 28-11). Proximal corpus cavernosum to spongiosum (CC-CS) shunt procedures require a trans-scrotal or transperineal approach (Quackles, 1964). There are no data comparing bilateral (Sacher et al, 1972) and unilateral CC-CS shunts (Quackles, 1964). Typically, bilateral shunts are staggered; the right side and left side are separated by a distance of at least 1 cm in an effort to minimize the risk of urethral stricture at the point of CC-CS communication (Fig. 28-12). If

Figure 28-12. Bilateral shunts are staggered. The right and left sides are separated by a distance of at least 1 cm in an effort to minimize the risk of urethral stricture at the point of corpus cavernosum to spongiosum communication (Sacher et al, 1972). (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

proximal shunting fails, some have advocated saphenous vein bypass or deep dorsal vein shunt (Fig. 28-13). A wedge of tunica albuginea is removed and the vein is anastomosed end to side of CC. There are no comparative trials of vein shunting for ischemic priapism. Authors have described a significant risk of saphenofemoral vein thrombus and pulmonary embolism with vein shunting (Kandel et al, 1968).

Immediate Implantation of Penile Prosthesis

Unfortunately, the natural history of untreated ischemic priapism or priapism refractory to interventions is severe fibrosis, penile length loss, and complete ED (see Fig. 28-1). Kelami (1985) described the implantation of the Small-Carrion penile prosthesis through an infrapubic incision in the management of postpriapic ED. Bertram and colleagues (1985) described six postpriapic cases of penile prosthesis; five of the six men had successful implantation of semirigid prostheses. Both groups described extensive corporal fibrosis and suggested that semirigid implants were preferable because inflatable implants would not overcome the corporal fibrosis sufficiently to erect the penis. Douglas and colleagues (1990) reported on penile prosthesis in five SCD postpriapic men; they described a surgical technique of tunneling and corporal excavation. Inadvertent damage to the tunica albuginea was common, as was subsequent migration of hardware; 11 additional procedures were required after the initial implants. The average time from priapism to implant in Douglas's series was 4 years. Monga and

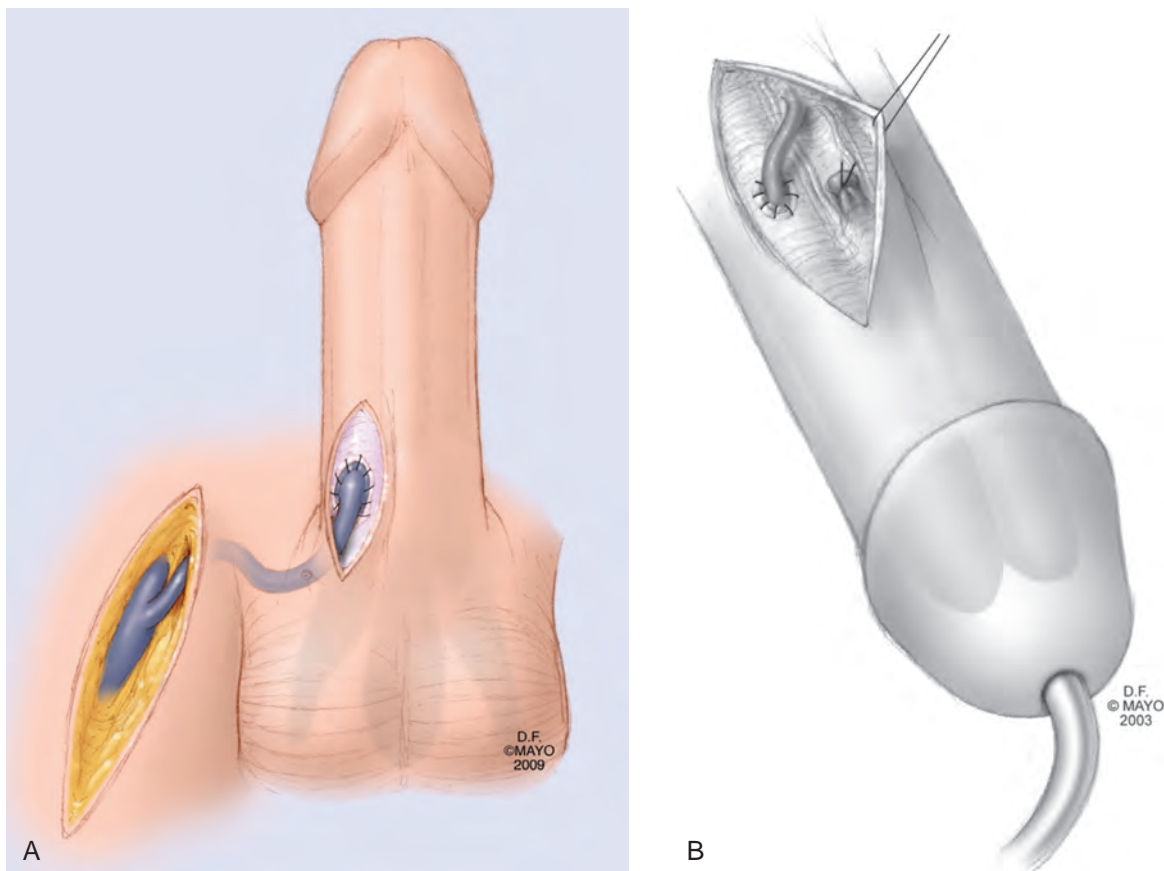

Figure 28-13. A, Venous bypass to control ischemic priapism was first described by Grayhack and colleagues in 1964. The Grayhack shunt mobilizes the saphenous vein below the junction of the femoral vein and anastomoses the vein end to side into the corpus cavernosum. B, Deep dorsal vein (DDV) shunt with distal ligation of DDV and anastomosis of proximal DDV to corpus cavernosum. A wedge of tunica albuginea is removed. KEY POINTS: SURGICAL MANAGEMENT OF ISCHEMIC PRIAPISM

- Shunt surgery should be considered for all patients with ischemic priapism in whom aspiration and ICI of α -adrenergics has failed.
- Patients should be counseled that erectile function outcomes decline significantly when ischemic priapism has lasted longer than 24 hours and that complete ED is anticipated if ischemic priapism persists for longer than 36 hours.
- The objective of shunt surgery is reoxygenation of the cavernous smooth muscle.
- The key factors determining successful surgical reversal of ischemic priapism are evacuation of thrombus, patency of shunt, and resumption of cavernous inflow.
- A distal cavernoglanular shunt should be the first choice of shunting procedures.
- Percutaneous distal shunting is less invasive than open distal shunting and may be performed with local anesthetics.
- There are a number of distal shunting procedures, and the surgeon should be familiar with these procedures and their complications.
- Open distal shunting should be considered if percutaneous shunting fails. There are no comparative trials of safety, efficacy, or erectile function outcomes for percutaneous versus open distal shunting techniques.
- If distal shunting fails, then proximal shunting is recommended. Proximal shunting establishes a communication between the CC and corpus spongiosum at the base of the penis. The surgeon must be aware of the unique anatomic relationship between the corpus spongiosum and urethra.
- Shunting may also be accomplished with vein grafting to the CC. Venous shunts have increased the risk of thromboembolism.
- After medical or surgical reversal of ischemic priapism, penile tumescence rather than complete flaccidity may be evident. A phenomenon of conversion from ischemic priapism to HFP has been described. In cases in which the examination findings may be equivocal, CDU or cavernous blood gas is recommended to demonstrate patency of the shunt and restoration of cavernous inflows.
- After shunting, follow up with the patient regarding erectile function and any subsequent ED therapies.

colleagues (1996) described implants in young SCD patients (six patients, average age 26); inflatable implants were placed to both treat ED and circumvent ongoing episodes of stuttering priapism. These researchers suggested that both potency and recurrent episodes of ischemic priapism could be managed by “early” implantation. Some have suggested performing an immediate penile prosthesis procedure in the acute management of ischemic priapism in patients in whom sympathomimetic intracavernous therapies and shunting have failed (Rees et al, 2002). There are two distinct advantages to immediate implantation: corporal fibrosis is not yet established, and penile length may be preserved. The exact time point at which prosthetic insertion becomes a reasonable option for managing ischemic priapism is unclear. Should medical management of ischemic priapism be followed by distal percutaneous shunt, by open distal shunt, and subsequently by proximal shunting before penile implant? Should men with delayed presentation of ischemic priapism and evident corporal thrombus be triaged to an immediate penile implant procedure? What is clear is that any discussion pertaining to early prosthesis insertion should be documented and should include a comprehensive review of the theoretic advantages and actual risks. Compared with prosthesis insertion in a typical patient with ED, there are significantly higher rates of complications noted in priapism cases: infection, urethral injury, device migration, device erosion, and revision surgeries. The surgeon must be familiar with the additional technical concerns posed by weaknesses in the tunica albuginea in the region of prior shunts.

The advantages of early penile implantation in the acute management of ischemic priapism are preservation of penile length and technically easier implant insertion. Delayed placement of penile prosthesis is technically challenging because of corporal fibrosis (see Fig. 28-1B to D). Ralph and colleagues (2009) reported on 50 patients with ischemic priapism. In all patients, conservative management with the instillation of α -adrenergic agents (200 μ g phenylephrine repeated to a maximum dose of 1500 μ g) failed. Unsuccessful shunts were performed in 13 of 50 cases (Ralph et al, 2009). Mean duration of priapism was 209 hours (range 24 to 720 hours). All patients had evidence of cavernous thrombus and smooth muscle necrosis on MRI, and all 50 underwent insertion of penile prosthesis in the acute setting of refractory ischemic priapism. Revision rates were significantly high, at 24% (12 of 50 patients). The infection rate of 6% was also notably high and likely related to multiple factors including ischemic tissues and preceding penile interventions (Fig. 28-14). The same surgical group recently

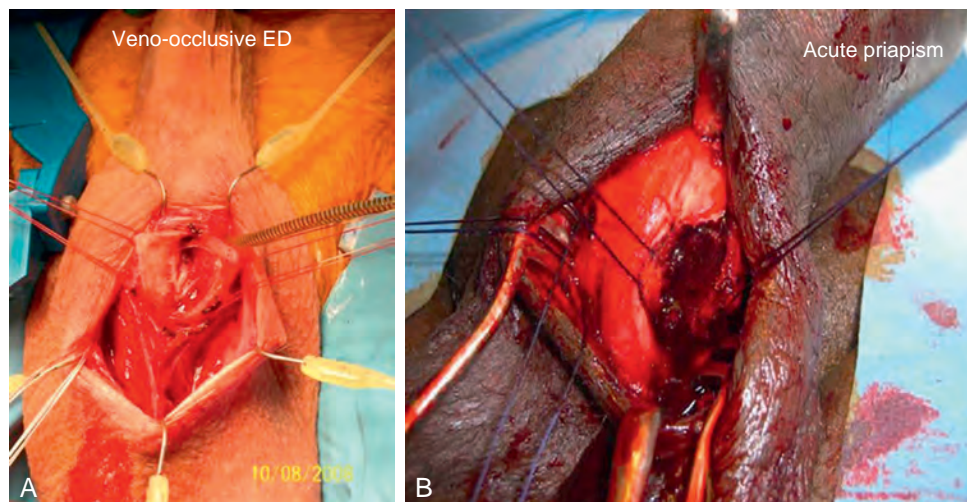

Figure 28-14. A penoscrotal surgical approach for insertion of inflatable penile implant in a white male patient with severe veno-occlusive erectile dysfunction (ED) (A) and a sickle cell disease patient with acute ischemic priapism refractory to pharmacologic interventions and shunting for 48 hours (B). (A, Courtesy G. A. Broderick, MD; B, courtesy David J. Ralph, MD.)

KEY POINTS: SURGICAL MANAGEMENT OF ISCHEMIC PRIAPISM WITH IMMEDIATE PENILE IMPLANT

- The natural history of untreated ischemic priapism or priapism refractory to interventions is severe fibrosis, penile length loss, and complete ED.
- The advantages of early penile implantation in the acute management of ischemic priapism are preservation of penile length and easier insertion.
- Document baseline erectile function, duration of priapism, history of stuttering, and prior interventions.
- Consider penile prosthesis in the following circumstances:
 - Aspiration and sympathomimetic ICI have failed.
 - Distal and proximal shunting procedures have failed.
 - Ischemia has been present for longer than 36 hours.
- Consider an MRI before surgery or corporal biopsy at the time of implant to document corporal smooth muscle necrosis.
- There are higher rates of revision surgery and complications noted in priapism cases resulting from infection, urethral injury, device migration, and device erosion.

compared two cohorts of patients undergoing penile implant for refractory ischemic priapism. An early insertion cohort was operated on at a mean of 7 days after onset of priapism, and the delayed cohort was operated on at a mean of 5 months after priapism. In the early insertion group, satisfaction and ability to have intercourse was 96%; in the delayed group, corporal fibrosis made surgery technically more difficult and overall patient satisfaction was 60% (Zacharakis et al, 2014a).

INTERVENTIONAL ANGIOGRAPHY IN THE MANAGEMENT OF ARTERIAL (NONISCHEMIC, HIGH-FLOW) PRIAPISM

Arterial priapism is not an emergency. Spontaneous resolution or response to conservative therapy has been reported in up to 62% of published series (Montague et al, 2003; Pryor et al, 2004). Persistent partial erection from HFP may be evident for months to years, without adverse impact on erectile function (Bastuba et al, 1995). Kumar and colleagues (2006) described a case of HFP in a 24-year-old patient 10 days after straddle injury on a bicycle. The patient had no erection for the first 4 days after injury. Examination revealed a tumescent penis that was compressible. Penile aspiration and blood gas analysis revealed oxygenated corporal blood. CDU of the cavernous artery revealed arteriosinusoidal fistula. Partial erection spontaneously resolved 4 days after diagnostic evaluation, with the patient reporting normal erections 2 weeks later. The authors hypothesized that in patients with blunt penile and perineal trauma, an arteriolacunar fistula forms; these fistulae, unlike arteriovenous communications, may spontaneously resolve because the less rigid walls of the lacunae are prone to spontaneous thrombosis. Onset of HFP is typically delayed for 72 hours after injury. The erection is partial, not rigid, and not painful. Although the site of perineal trauma may have hematoma, spreading of the hematoma to the shaft should raise suspicion of rupture of tunica albuginea; this would be highly unusual in blunt perineal (straddle) injury. The pathophysiology of HFP is unregulated arteriolacunar fistula from disruption or crush injury to terminal branches of the cavernous artery. Fistula is typically unilateral. Because there is no restriction of venous outflow, erection is partial and bendable. Patients do report additional engorgement with sexual stimulation, with return to partial erection after climax.

There are no comparative outcome studies of intervention versus conservative management in HFP; there are sufficient case descriptions, especially in children, to recommend initial watchful

Figure 28-15. Color Doppler ultrasonography of the penis and perineum is recommended in the evaluation of priapism when the history or examination findings suggest penile trauma (A). Doppler sonography for localization of a fistula correlates well with selective pudendal angiography (B to E); a characteristic fistula blush is shown (B and D), along with normal arteriograms (C and E). waiting (Nehra, 2006). Initial observation is recommended for this type of priapism. Conservative measures include ice applied to the perineum and site-specific compression. Cavernous aspiration has only a diagnostic role in HFP. Repeated aspirations, injection, and irrigation with intracavernous sympathomimetics have no role in the treatment of nonischemic priapism.

Patients demanding immediate relief can be offered selective arterial embolization. The pathognomonic arteriographic finding is an arteriolacunar fistula; a characteristic intracavernosal cone-shaped blush of contrast is seen at the site of the cavernous artery or arteriole laceration (Fig. 28-15). Selective internal pudendal catheterization and subsequent embolization have been reported with various agents: microcoils, polyvinyl alcohol, *N*-butylcyanoacrylate, gel-foam, and autologous blood clot (Kuefer et al, 2005). Permanent materials pose a greater theoretic risk of ED; many authors recommend use of autologous blood clot and absorbable gels (Pryor et al, 2004; Kim et al, 2007). Autologous blood clot has a low risk of foreign body reaction, or antigenicity; it is a temporary occlusive agent and should permit recanalization of the cavernous artery (Park et al, 2001). The success rates with selective pudendal

artery catheterization followed by embolization are quite high (89% to 100%), regardless of the embolization material used (Kuefer et al, 2005; Numan et al, 2008). Similar results have been reported by others (Savoca et al, 2004; Alexander Tønseth et al, 2006). Normal postembolization erectile function has been reported in 75% to 86% of patients (Cakan et al, 2006; Numan et al, 2008). It should be noted that a single treatment of embolization carries a recurrence rate of 30% (Ciampalini et al, 2002; Gandini et al, 2004; Ozturk et al, 2009). Although ultimately successful, embolization of HFP may require retreatment. The most notable side effect of bilateral arterial embolization is ED. Recurrence of HFP after embolization may be caused by recanalization of the embolized fistula or unmasking of a fistula in the contralateral cavernous artery. Although it was previously reported that non-permanent embolization materials cause less ED than permanent ones (5% vs. 39%), reports describing use of the IIEF in evaluation of postembolization erectile function note similar rates of ED—15% and 20% (Savoca et al, 2004; Alexander Tønseth et al, 2006). Other reported adverse effects include penile gangrene, gluteal ischemia, purulent cavernositis, and abscess of the perineum (Hakim et al, 1996; Sandock et al, 1996).

Puppo and colleagues (1985) compared perineal duplex ultrasound and selective internal pudendal arteriography, showing excellent sensitivity of ultrasound in detecting arteriolacunar fistulae that were seen angiographically (12 of 12 cases). Several reports have described combined ultrasound-guided compression with selective arterial embolization to increase success rates in the treatment of nonischemic priapism (Hatzichristou et al, 2002; Bartsch et al, 2004; Cakan et al, 2006). If the follow-up clinical examination is equivocal for recurrence of HFP, a perineal duplex Doppler ultrasound can determine the need for repeat arteriography and embolization (Kim et al, 2007).

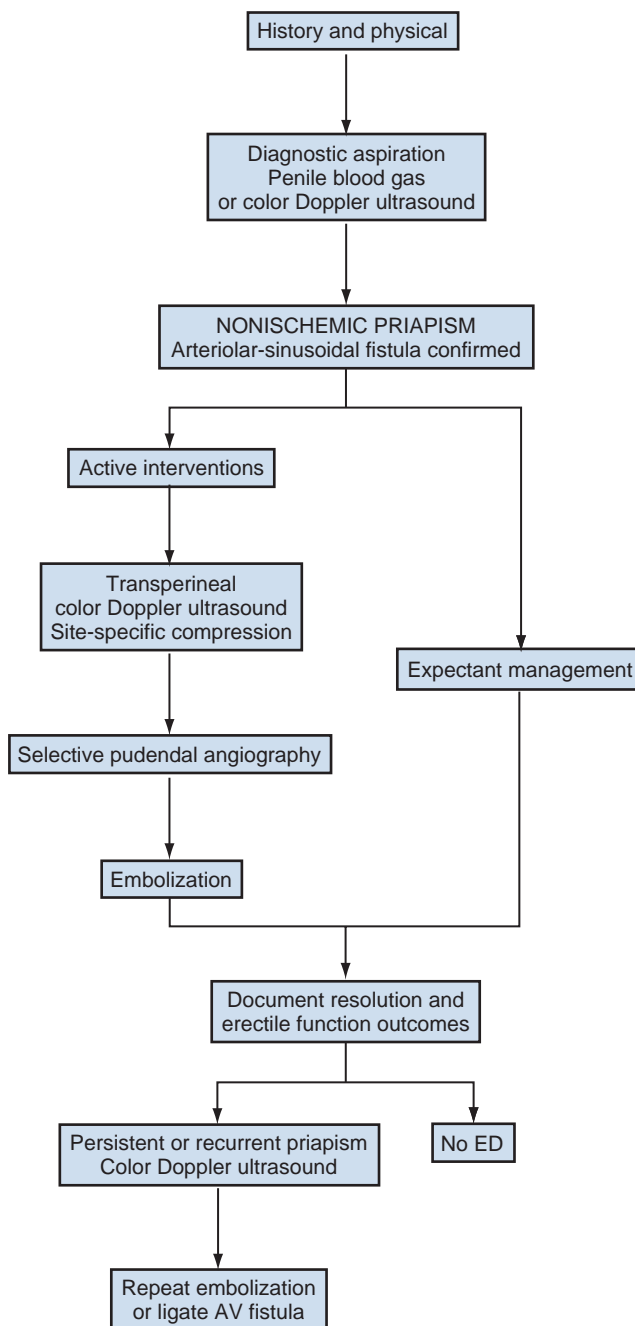

SURGICAL MANAGEMENT OF ARTERIAL (NONISCHEMIC, HIGH-FLOW) PRIAPISM

Arterial priapism is not a urologic emergency. HFP is painless, and there have been reports of partial erection persisting for years (Nehra, 2006). Any intervention must follow a comprehensive discussion with the patient regarding risks and benefits of any of the procedures advocated by the clinician. In cases of long-standing arterial priapism in which a pseudocapsule around the fistula has developed, surgical ligation has been reported to be successful. Formation of a pseudocapsule may take weeks to months after trauma. Corporal exploration before the formation of a pseudocapsule may result in ligation of the cavernous artery

rather than selective ligation of the fistula. Currently this intervention is reserved for patients who do not wish to pursue expectant management or who are poor candidates for angioembolization. It is also reserved for patients who refuse the procedure; for patients in places where technology is not available; and for patients in whom angioembolization has failed (Ji et al, 1994; Berger et al, 2001; Mulhall, 2006). The surgical approach is transcorpal. Intraoperative Doppler ultrasound guidance is recommended (Fig. 28-16).

SUMMARY

Priapism is a full or partial erection that persists more than 4 hours beyond sexual stimulation and orgasm or is unrelated to sexual stimulation. Prompt diagnosis and appropriate management are

KEY POINTS: EVALUATION AND MANAGEMENT OF HIGH-FLOW PRIAPISM

- Arterial priapism is not an emergency and may be managed expectantly.
- Diagnosis of HFP is best made by penile or perineal CDU.
- Penile aspiration and injection of α -adrenergic agents is not recommended for HFP.
- Angioembolization should be preceded by a thorough discussion of chances for spontaneous resolution, risks of treatment-related ED, and lack of significant consequences expected from delaying interventions.
- Overall success rates with embolization are high, although a single treatment carries a recurrence rate of 30% to 40%.
- When angioembolization fails or is contraindicated, surgical ligation is reasonable.
- Formation of a pseudocapsule at the site of a sinusoidal fistula may take weeks to months after trauma.
- CDU guidance is recommended during exploration to locate fistulae.

necessary to spare patients ineffective interventions and optimize erectile function outcomes. Ischemic priapism (veno-occlusive, low-flow) is a persistent erection marked by rigidity of the CC. In ischemic priapism there are time-dependent changes in the corpora with progressive hypoxia, hypercarbia, and acidosis. Ischemic priapism is a urologic emergency. Treatment for ischemic priapism is administered in stepwise manner: decompression of the corpora by needle aspiration, injection and irrigation with a dilute sympathomimetic drug, surgical shunting, and consideration of immediate penile implant in refractory cases. Ischemic priapism is a common pathologic consequence of SCD. Stuttering ischemic priapism describes a pattern of prolonged morning erections that are unwanted and painful in boys and adolescents with SCD. Any patient who has experienced an episode of ischemic priapism is also at risk for stuttering priapism. HFP (nonischemic priapism, arterial priapism) is a persistent erection caused by unregulated cavernous arterial inflow. Typically, the corpora are tumescent but not rigid and the penis is not painful. A history of blunt trauma (a straddle injury) or an iatrogenic needle injury to the penis is common. The cavernous environment in HFP does not become ischemic, and cavernous blood gases do not show hypoxia, hypercarbia, or acidosis. HFP, once properly diagnosed, does not require emergent treatment. Urologists intervening to treat priapism should use standardized questionnaires to document the history of the prolonged erection: onset, trauma, medical history of blood dyscrasias, use of illicit substances, prior events, prepriapism erectile function, recurrence after each intervention, and recovery of erectile function. Documenting erectile function outcomes on the basis of duration of ischemic priapism, time to interventions, and types of interventions will establish evidence-based guidance on how and when to apply those interventions.

Anatomy and Physiology of the Ejaculatory Response

Premature Ejaculation

Delayed Ejaculation, Anejaculation, and Anorgasmia

Retrograde Ejaculation

Painful Ejaculation

Postorgasmic Illness Syndrome

Conclusion

Ejaculatory dysfunction is one of the most common male sexual disorders. The spectrum of ejaculatory dysfunction extends from premature ejaculation (PE), through delayed ejaculation, to a complete inability to ejaculate (known as anejaculation) and includes retrograde ejaculation, painful ejaculation, and the recently described postorgasmic illness syndrome (POIS).

The sexual response cycle comprises the four interactive stages of desire, arousal, orgasm, and resolution. During sexual activity, increasing levels of sexual arousal reach a threshold that triggers the ejaculatory response, which then typically terminates the sexual episode for the male. The perception of the striated muscle contractions and resulting semen expelled during ejaculation, mediated through sensory neurons in the pelvic region, gives rise to the experience of orgasm, a distinct cortical event, experienced phenomenologically both cognitively and emotionally.

Ejaculatory latency, the time extending from the onset of penile stimulation to the moment of ejaculation, represents a continuum of time that shows variation across men and, within men, across situations. Although the great majority of men appear to reach ejaculation and orgasm after several minutes of penile vaginal stimulation and are, along with their partners, quite satisfied with the latency of their ejaculatory response, others report dissatisfaction. Specifically, some men ejaculate very rapidly after, or sometimes even before, penetration and do so with minimal stimulation. Others may ejaculate only with great difficulty or not at all, even after prolonged stimulation.

ANATOMY AND PHYSIOLOGY OF THE EJACULATORY RESPONSE

The ejaculatory reflex comprises sensory receptors and areas, afferent pathways, cerebral sensory areas, cerebral motor centers, spinal motor centers, and efferent pathways (Fig. 29-1). Neurochemically, this reflex involves a complex interplay between central serotonergic and dopaminergic neurons, with secondary involvement of cholinergic, adrenergic, oxytocinergic, and γ -aminobutyric acid (GABA) neurons.

Based on functional, central, and peripheral mediation, the ejaculatory process is typically subdivided into three phases: emission, ejection (or penile expulsion), and orgasm. Emission consists of contractions of seminal vesicles and the prostate, with expulsion of sperm and seminal fluid into the posterior urethra, and is mediated by sympathetic nerves (T10 to L2). Ejection is mediated by somatic nerves (S2 to S4), and involves pulsatile contractions of the bulbocavernosus and pelvic floor muscles together with relaxation of the external urinary sphincter. Ejection also involves a

sympathetic spinal cord reflex, on which there is limited voluntary control. The bladder neck closes to prevent retrograde flow; the bulbocavernosus, bulbospongiosus, and other pelvic floor muscles contract rhythmically, and the external urinary sphincter relaxes. Intermittent contraction of the urethral sphincter prevents retrograde flow into the proximal urethra (Yeates, 1987). Orgasm is the result of cerebral processing of pudendal nerve sensory stimuli resulting from increased pressure in the posterior urethra, sensory stimuli arising from the verumontanum, and contraction of the urethral bulb and accessory sexual organs.

Many neurotransmitters are involved in the control of ejaculation, including dopamine, norepinephrine, serotonin, acetylcholine, oxytocin, GABA, and nitric oxide (McMahon et al, 2004a). Of the many studies conducted to investigate the role of the brain in the development and mediation of sexual functioning, dopamine and serotonin have emerged as essential neurochemical factors. Whereas dopamine promotes seminal emission/ejaculation via D_2 receptors, serotonin is inhibitory. Serotonergic neurons are widely distributed in the brain and spinal cord and are predominantly found in the brainstem, raphe nuclei, and the reticular formation. Currently, multiple serotonin (5-HT) receptors have been characterized: 5-HT_{1A}, 5-HT_{1B}, 5-HT_{2A}, 5-HT_{2B}, etc. (Peroutka and Snyder, 1979). Stimulation of the 5-HT_{2C} receptor with 5-HT_{2C} agonists results in delay of ejaculation in male rats, whereas stimulation of postsynaptic 5-HT_{1A} receptors results in shortening of ejaculation latency (Ahlenius et al, 1981), leading to the hypothesis that men with PE may have hyposensitivity of 5-HT_{2C} and/or hypersensitivity of the 5-HT_{1A} receptor (Waldinger, 2002; Waldinger and Oliver, 2005).

PREMATURE EJACULATION

Classification of Premature Ejaculation

In 1943 Schapiro proposed classification of PE into two types, B and A (Schapiro, 1943). In 1989 Godpodinoff renamed both types as lifelong (primary) and acquired (secondary) PE (Godpodinoff, 1989). Over the years, other attempts to specify subtypes have occurred (e.g., global vs. situational, the effect of a substance, etc.).

Lifelong PE is a syndrome characterized by a cluster of core symptoms, including early ejaculation at nearly every intercourse within 30 to 60 seconds in the majority of cases (80%) or between 1 to 2 minutes (20%), with every or nearly every sexual partner and from the first sexual encounters onward (Waldinger, 1998; McMahon, 2002).

Acquired PE differs in that men develop early ejaculation at some point in their life, which is often situational, having previously had normal ejaculation experiences. The main distinguishing features between presentations of these two syndromes are the

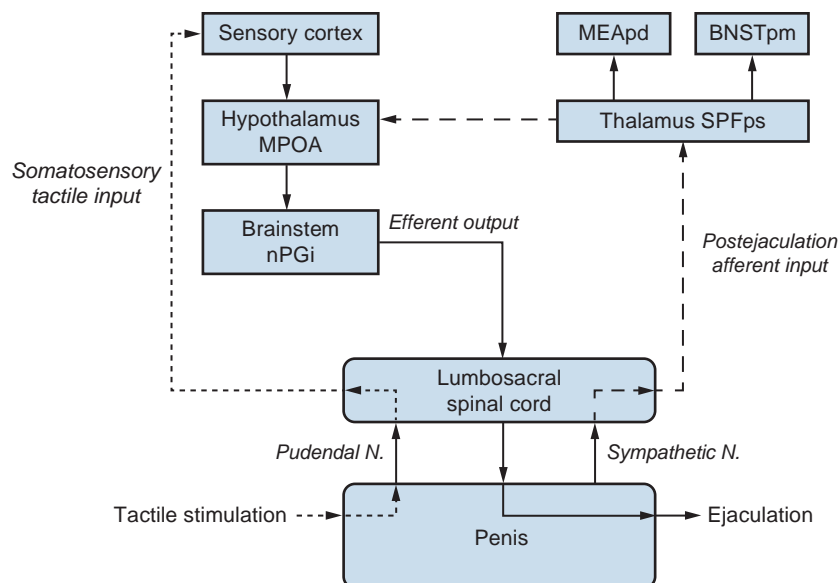

Figure 29-1. Central nervous system areas involved before, during, and after ejaculation. Somatosensory tactile input from the penis/genitals ascends to the cerebral cortex. Efferent pathways project from the hypothalamus to the sacral spinal cord and genitals. After ejaculation, information is returned from the genitals to several brain areas. BNSTpm, posteromedial bed nucleus of stria terminalis; MEApd, posterodorsal medial amygdala; MPOA, medial preoptic area; N, nerve; nPGi, nucleus paragigantocellularis; SPFPs, medial parvocellular subparafascicular nucleus of thalamus. (From Waldinger MD. The neurobiological approach to premature ejaculation. *J Urol* 2002;168:2359–67.)

time of onset of symptoms and the reduction in previously normal ejaculatory latency of acquired PE.

Community-based normative intravaginal ejaculation latency time (IELT) research and observational studies of men with PE demonstrated that although IELTs of less than 1 minute have a low prevalence of approximately 2.5% in the general population, a substantially higher percentage of men with normal IELT report PE (Patrick et al, 2005; Waldinger et al, 2005a, 2009). To take account of this diversity, Waldinger and Schweitzer (2006b, 2008) proposed a new classification of PE in which four PE subtypes are distinguished on the basis of the duration of the IELT, frequency of reports, and course in life. In addition to lifelong PE and acquired PE, this classification includes natural variable PE (or variable PE) and premature-like ejaculatory dysfunction (or subjective PE). Men with variable PE occasionally experience an early ejaculation. It should not be regarded as a disorder, but as a natural variation of the ejaculation time in men (Waldinger, 2013). On the other hand, men with subjective PE report PE while actually having a normal or even extended ejaculation time (Waldinger, 2013). The report of PE in these men is probably related to psychological and/or cultural factors. In contrast, the consistent early ejaculations of lifelong PE suggest an underlying neurobiologic functional disturbance, whereas the early ejaculation of acquired PE is more related to underlying medical causes. Serefoglu and colleagues (2010, 2011) confirmed the existence of these four PE subtypes in a cohort of men in Turkey. Recently, Zhang and associates (2013) and Gao and colleagues (2013) using a similar methodology confirmed similar prevalence rates of the four PE subtypes in China to that reported by Serefoglu and associates (2010, 2011). This new classification and continued research into the diverse phenomenology, cause, and pathogenesis of PE are expected to provide a better understanding of the four PE subtypes (Waldinger and Schweitzer, 2008). Although the pathogenesis of lifelong and acquired PE differs, the presence of shared dimensions, such as a lack of ejaculatory control and the presence of negative personal consequences, suggests a potential for a single unifying definition of both lifelong and acquired PE. With

continued research into the two other PE subtypes, variable PE and subjective PE, it may be appropriate to expand this unifying definition in the future.

Definition of Premature Ejaculation

Research into the treatment and epidemiology of PE depends heavily on how PE is defined. The medical literature contains several univariate and multivariate operational definitions of PE (Masters and Johnson, 1970; American Psychiatric Association, 1994; World Health Organization, 1994; Metz and McCarthy, 2003; Colpi et al, 2004; McMahon et al, 2004b; Montague et al, 2004; Jannini et al, 2005; Waldinger et al, 2005b; McMahon et al, 2008b) (Table 29-1). Each of these definitions characterizes men with PE using all or most of the accepted dimensions of this condition: ejaculatory latency, perceived ability to control ejaculation, reduced sexual satisfaction, personal distress, partner distress, and interpersonal or relationship distress. **None of these definitions was supported by evidence-based clinical research.**

These authority-based definitions are discussed in detail on the Expert Consult website.

International Society for Sexual Medicine Definition of Premature Ejaculation

In the last decade, substantial progress has been made in the development of evidence-based methodology for PE epidemiologic and drug treatment research using the objective IELT and subjective validated patient-reported outcome (PRO) measures. In October 2007, the International Society for Sexual Medicine (ISSM) convened an initial meeting of the first Ad Hoc ISSM Committee for the Definition of Premature Ejaculation to develop the first contemporary, evidence-based definition of lifelong PE. Evidence-based definitions seek to limit errors of classification and thereby increase the likelihood that existing and newly developed therapeutic strategies are truly effective in carefully selected dysfunctional

Traditional Definitions of Premature Ejaculation

During the period of 1920 to 1960, the absence of any scientific publications proposing a definition of PE reflects the scarcity of prevalence data. Based on the limited published literature, a man was considered to have PE when he ejaculated within seconds or within approximately a minute of vaginal penetration (Waldinger, 2006). In the 1970s, despite an absence of empirical data, Masters and Johnson (1970) rejected this ejaculation latency proposal and defined PE as a man's inability to satisfy his female partner on more than 50% of sexual events. Their rejection of the ejaculation time criterion has led to debate on "objective criteria" and "subjective criteria" of PE (Waldinger and Schweitzer, 2008). Typical "objective" criteria include the ejaculation latency time and the number of penile thrusts. "Subjective" criteria are measures of self-efficacy, including "diminished feelings of control" and "ejaculation at moments without wishing it."

These opposing constructs have served as the framework for the development of the various definitions proposed in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) by the American Psychiatric Association (Waldinger and Schweitzer, 2006a, 2006b).

The first official definition of PE was established in 1980 by the American Psychiatric Association in the DSM-III. PE was defined as "Ejaculation that occurs before the individual wishes it, because of recurrent and persistent absence of reasonable voluntary control of ejaculation and orgasm during sexual activity" (American Psychiatric Association 1980). However, because of disagreement on the criterion of "reasonable voluntary control," this criterion was removed in the subsequent DSM-III-R and DSM-IV definitions (American Psychiatric Association, 1987, 2000) and replaced by the criterion of a "short ejaculation time." The DSM-IV-TR defined PE as a "Persistent or recurrent ejaculation with minimal sexual stimulation before, on, or shortly after penetration and before the person wishes it. The clinician must take into account factors that affect the duration of the excitement phase such as age, novelty of the sexual partner or situation, and recent frequency of sexual activity" and requires for the diagnosis that "the disturbance causes marked distress or interpersonal difficulty" (American Psychiatric Association, 2000). Thus DSM-III contains the criterion of control but not time, whereas subsequent DSM-III-R, DSM-IV, and DSM-IV-TR definitions contained the criterion of time but not control (Waldinger and Schweitzer, 2006a, 2006b).

The DSM III/IV definitions of PE were largely accepted with little discussion, despite having no evidence-based medical support (St. Lawrence and Madakasira, 1992). After the introduction of evidence-based PE pharmacotherapy, the validity of the DSM definitions was the subject of debate with a substantial polarization of opinion. The inclusion of words such as *persistent*, *recurrent*, *minimal*, and *shortly after* rendered the DSM definitions vague, multi-interpretable, and lacking quantification (O'Donohue et al, 1993; Waldinger, 2002; Althof and Symonds, 2007). Concerns about the validity and application of the DSM-IV-TR definition were also expressed by regulatory agencies such as the U.S. Food and

Drug Administration, which regarded the lack of evidence-based criteria as a potential obstacle to interpret and assess data from clinical trials of PE investigational drugs.

The World Health Organization 1992 ICD-10 defines PE as "The inability to control ejaculation sufficiently for both partners to enjoy sexual interaction" and as "an inability to delay ejaculation sufficiently to enjoy lovemaking, and manifest as either of the following: (1) occurrence of ejaculation before or very soon after the beginning of intercourse (if a time limit is required: before or within 15 seconds of the beginning of intercourse) and (2) ejaculation occurs in the absence of sufficient erection to make intercourse possible" (World Health Organization, 1994). The ICD-10 uses both the criterion of "control" and a "very short" ejaculation time, and quantifies the ejaculation time to maximally 15 seconds after penetration. Although the ICD-10 provides an objective definition of PE, evidence to support a latency cutoff of 15 seconds was not provided (Waldinger and Schweitzer, 2006a, 2006b). Furthermore, the ICD-10 use of the criterion of ejaculation that occurs within 15 seconds restricts the application of the criterion of control (Waldinger and Schweitzer, 2006a, 2006b).

The lack of consensus as to what constitutes PE hampered clinical practice and basic and clinical research into the cause and management of this condition. The results of PE epidemiologic and drug treatment clinical trials are reliable, interpretable, and capable of being generalized to patients only when consistent objective physiologic measures or sensitive, validated outcome assessment instruments are used as study end points (McMahon, 2008a) in well-defined and consistent populations in whom lifelong PE, acquired PE, or PE with comorbid erectile dysfunction (ED) are treated as separate PE subgroups.

The absence of a specific ejaculation time cutoff point to operationalize "shortly after penetration or before the person wishes" led to the incorrect application of the DSM definitions in epidemiologic and clinical research (Waldinger et al, 1998; Patrick et al, 2005; Giuliano et al, 2008; McMahon, 2008b). Giuliano and colleagues (2008) reported the IELT of men with DSM-IV-TR–diagnosed PE ranged from 0 seconds (antiportal ejaculation) to almost 28 minutes, with 44% of subjects having an IELT of 2 minutes or longer and 25% of 4 minutes or longer. This study demonstrates that a subject with DSM-IV-TR–diagnosed PE has a 44% risk for not having PE if a PE diagnostic threshold IELT of 2 minutes, as suggested by community-based normative IELT trial, is used (Waldinger et al, 2005a).

Waldinger and associates (1998), in a number of studies in cohorts of heterosexual men with lifelong PE with prospective stopwatch IELT measurement, showed that approximately 90% of men seeking treatment for lifelong PE ejaculated within 1 minute after penetration and approximately 10% ejaculated between 1 and 2 minutes. These data were confirmed by McMahon (2002) in a retrospective questionnaire analysis of a large cohort of men with lifelong PE. These data support the proposal that lifelong PE is characterized by an IELT of less than or approximately 1 minute after vaginal penetration.

TABLE 29-1 Definitions of Premature Ejaculation (PE)

DEFINITION	SOURCE
PE is a male sexual dysfunction characterized by ejaculation that always or nearly always occurs before or within 1 min of vaginal penetration (lifelong PE) or a clinically significant and bothersome reduction in latency time, often to $\sim \leq 3$ min (acquired PE), the inability to delay ejaculation on all or nearly all vaginal penetrations, and negative personal consequences, such as distress, bother, frustration, and/or the avoidance of sexual intimacy.	International Society of Sexual Medicine, 2014
Lifelong PE is a male sexual dysfunction characterized by ejaculation that always or nearly always occurs before or within 1 min of vaginal penetration, the inability to delay ejaculation on all or nearly all vaginal penetrations, and negative personal consequences, such as distress, bother, frustration, and/or the avoidance of sexual intimacy.	McMahon et al (ISSM), 2008b
A persistent or recurrent pattern of ejaculation occurring during partnered sexual activity within ~ 1 min after vaginal penetration and before the individual wishes it. This symptom must have been present for at least 6 mo and must be experienced on almost all or all ($\sim 75\%$ -100%) occasions of sexual activity. It causes clinically significant distress in the individual.	American Psychiatric Association (DSM-5), 2013
Persistent or recurrent ejaculation with minimal sexual stimulation, before, on, or shortly after penetration and before the person wishes it. The condition also must cause marked distress or interpersonal difficulty and cannot be due exclusively to the direct effects of a substance.	American Psychiatric Association (DSM-IV-TR), 2000
For individuals who meet the general criteria for sexual dysfunction, the inability to control ejaculation sufficiently for both partners to enjoy sexual interaction, manifest as either the occurrence of ejaculation before or very soon after the beginning of intercourse (if a time limit is required, before or within 15 secs) or the occurrence of ejaculation in the absence of sufficient erection to make intercourse possible. The problem is not the result of prolonged absence from sexual activity.	World Health Organization (ICD-10), 1994
The inability to control ejaculation for a “sufficient” length of time before vaginal penetration. It does not involve any impairment of fertility, when intravaginal ejaculation occurs.	Hatzimouratidis et al (EAU Guidelines on Disorders of Ejaculation), 2010
Persistent or recurrent ejaculation with minimal stimulation before, on, or shortly after penetration and before the person wishes it, over which the man has little or no voluntary control, which causes the man and/or his partner bother or distress.	McMahon et al (ICUD), 2004b
Ejaculation that occurs sooner than desired, either before or shortly after penetration, causing distress to one or both partners.	Montague et al (AUA Guideline on the Pharmacologic Management of PE), 2004
The man does not have voluntary, conscious control or the ability to choose in most encounters when to ejaculate.	Metz and McCarthy, 2003
The Foundation considers a man a premature ejaculator if he cannot control his ejaculatory process for a sufficient length of time during intravaginal containment to satisfy his partner in at least 50% of their coital connections.	Masters and Johnson, 1970
Men with an IELT < 1 min (belonging to the 0.5th percentile) have “definite” PE, and men with IELTs between 1 and 1.5 min (0.5th to 2.5th percentile) have “probable” PE (see Fig. 29-2). In addition, a grading of severity of PE should be defined in terms of associated psychological problems. Thus both definite and probable PE need further psychological subclassification in asymptomatic, mild, moderate, and severe PE.	Waldinger et al, 2005c
PE is diagnosed on the basis of the pathologic IELT, as measured by the stopwatch method, with a feeling of loss of voluntary control and/or distress or relational disturbances, as measured by PRO.	Jannini et al, 2005

AUA, American Urological Association; DSM-IV-TR, *Diagnostic and Statistical Manual of Mental Disorders* (4th edition, Text Revision); DSM-5, *Diagnostic and Statistical Manual of Mental Disorders* (5th edition); EAU, European Association of Urology; ICUD, International Consultation on Urological Diseases; IELT, intravaginal ejaculation latency time; ISSM, International Society of Sexual Medicine; PRO, patient-reported outcome.

populations (Metz and McCarthy, 2003). After critical evaluation of the published data, the committee unanimously agreed that the constructs that are necessary to define lifelong PE are time from penetration to ejaculation, inability to delay ejaculation, and negative personal consequences from PE, and they recommended the following definition (McMahon et al, 2008a):

Lifelong PE is a male sexual dysfunction characterized by the presence of all of these criteria: 1) ejaculation that always or

nearly always occurs prior to or within about 1 minute of vaginal penetration; 2) the inability to delay ejaculation on all or nearly all vaginal penetrations; and 3) negative personal consequences such as distress, bother, frustration, and/or the avoidance of sexual intimacy.

However, the committee was unable to identify sufficient published objective data to craft an evidence-based definition of acquired PE. The committee anticipated that future studies would

generate sufficient data to develop an evidence-based definition for acquired PE.

In April 2013 the ISSM convened a second Ad Hoc ISSM Committee for the Definition of Premature Ejaculation in Bangalore, India. The brief of the committee was to evaluate the current published data and attempt to develop a contemporary, evidence-based definition of acquired PE and/or a single unifying definition of both acquired and lifelong PE. Members unanimously agreed that although lifelong and acquired PE are distinct and different demographic and etiologic populations, they can be jointly defined, in part, by the constructs of time from penetration to ejaculation, inability to delay ejaculation, and negative personal consequences from PE. The committee agreed that the presence of these mutual constructs was sufficient justification for the development of a single unifying definition of both lifelong and acquired PE. Finally, the committee determined that the presence of a clinically significant and bothersome reduction in latency time, often to approximately 3 minutes or less, was an additional key defining dimension of acquired PE.

The second Ad Hoc ISSM Committee for the Definition of Premature Ejaculation (2013) defined PE (lifelong and acquired PE) as a male sexual dysfunction characterized by the following:

- Ejaculation that always or nearly always occurs before or within approximately 1 minute of vaginal penetration (lifelong PE) or a clinically significant and bothersome reduction in latency time, often to approximately 3 minutes or less (acquired PE)
- The inability to delay ejaculation on all or nearly all vaginal penetrations
- Negative personal consequences, such as distress, bother, frustration, and/or the avoidance of sexual intimacy

The unified ISSM definition of lifelong and acquired PE represents the first evidence-based definition for these conditions. This definition should form the basis for the office diagnosis of lifelong PE and the design of PE observational and interventional clinical trials. It is limited to men engaging in vaginal intercourse because few studies are available on PE research in homosexual men or during other forms of sexual expression. This definition intentionally includes a degree of diagnostic conservatism and flexibility. The 1-minute IELT cutoff point for lifelong PE should not be applied in the most absolute sense, because approximately 10% of men seeking treatment for lifelong PE have IELTs of 1 to 2 minutes. The phrase “within approximately 1 minute” must be interpreted as giving the clinician sufficient flexibility to diagnose PE also in men who report an IELT as long as 90 seconds. Similarly, a degree of flexible clinical judgment is key to recognition and interpretation of a bothersome change in ejaculatory latency with reduction of premorbid latency to 3 minutes or less in men with acquired PE. Men who report these ejaculatory latencies but describe adequate control and no personal negative consequences related to their rapid ejaculation do not merit the diagnosis of PE.

 The rationale for the ISSM definition of lifelong and acquired PE is fully explored on the Expert Consult website.

Diagnostic and Statistical Manual of Mental Disorders (DSM-5) Definition of Premature Ejaculation

Based on the same data that supported the ISSM definition of lifelong PE, the recently published DSM-5 definition of PE (American Psychiatric Association, 2013) now includes an objective ejaculatory latency criterion. DSM-5 defines PE as follows:

A persistent or recurrent pattern of ejaculation occurring during partnered sexual activity within approximately 1 minute following vaginal penetration and before the individual wishes it. This symptom must have been present for at least 6 months and must be experienced on almost all or all (approximately 75%-100%) occasions of sexual activity. It causes clinically significant distress in the individual.

The DSM-5 definition of PE requires clinicians to specify PE as either lifelong or acquired and as generalized or situational. In addition, the DSM-5 definition of PE distinguishes between mild PE (ejaculation occurring within ~30 seconds to 1 minute of vaginal penetration), moderate PE (ejaculation occurring within ~15 to 30 seconds of vaginal penetration), and severe PE (ejaculation occurring before sexual activity, at the start of sexual activity, or within ~15 seconds of vaginal penetration).

Prevalence of Premature Ejaculation

Reliable information on the prevalence of lifelong and acquired PE in the general male population is lacking. PE has been estimated to occur in 4% to 39% of men in the general community (Reading and Wiest, 1984; Nathan, 1986; Spector and Boyle, 1986; Spector and Carey, 1990; Grenier and Byers, 1997; Laumann et al, 1999; Porst et al, 2007) and is often identified as the most common self-reported male sexual disorder (Jannini and Lenzi, 2005). However, a substantial disparity exists between the incidence of PE in epidemiologic studies that rely on patient self-report of PE and/or inconsistent and poorly validated definitions of PE (Laumann et al, 1999; Patrick et al, 2005; Giuliano et al, 2008) and, as suggested by community-based stopwatch studies of the IELT, the interval between penetration and ejaculation (Waldinger et al, 2005a). The latter demonstrates that the distribution of the IELT is positively skewed, with a median of 5.4 minutes (range, 0.55 to 44.1 minutes), decreases with age, varies across countries, and supports the notion that IELTs of less than 1 minute are statistically abnormal compared to those in men in the general Western population (Fig. 29-2) (Waldinger et al, 2005a).

Prevalence data derived from patient self-report will be appreciably higher than prevalence estimates based on clinician diagnosis using the more conservative ISSM definition of PE. The following studies demonstrate the varying prevalence estimates ranging from 30% down to 3%. Data from The Global Study of Sexual Attitudes and Behaviors (GSSAB), an international survey investigating the attitudes, behaviors, beliefs, and sexual satisfaction of 27,500 men and women 40 to 80 years of age, reported the global prevalence of PE (based on subject self-report) to be approximately 30% across all age groups (Nicolosi et al, 2004; Laumann et al, 2005). Perception of “normal” ejaculatory latency varied by country and differed when assessed by either the patient or the partner (Montorsi, 2005). A core limitation of the GSSAB survey stems from the fact that the youngest participants were 40 years of age, an age when the incidence of PE might be different from that of younger males (Jannini and Lenzi, 2005). Contrary to the GSSAB study, the Premature Ejaculation Prevalence and Attitude Survey found the prevalence of PE among men 18 to 70 years of age to be 22.7% (Porst et al, 2007). The real prevalence of PE is difficult to assess in clinical practice (Jannini and Lenzi, 2005).

Basile Fasalo and associates (2005) reported that 2658 of 12,558 men (21.2%) attending a free andrologic consultation self-diagnosed PE, the majority describing acquired PE (14.8%) and 4.5% describing lifelong PE. In contrast, Serefoglu and colleagues (2010) reported that the majority of PE treatment-seeking patients described lifelong PE (62.5%) compared to acquired PE (16.1%). Similar findings were reported by Zhang and coworkers (2013) who found that the majority of 1988 Chinese outpatients described lifelong PE (35.6%) or acquired PE (28.07%). These data provide evidence that patients with lifelong and acquired PE comprise the majority of the patients who seek treatment for PE. In addition, a disparity appears to exist between the incidence of the various PE subtypes in the general community and in men actively seeking treatment for PE.

Consistent with this notion, Serefoglu and colleagues (2011) subsequently reported an overall PE prevalence of 19.8% comprising lifelong PE (2.3%), acquired PE (3.9%), variable PE (8.5%), and subjective PE (5.1%). Using similar research methodology, Gao and associates (2013) reported that 25.80% of 3016 Chinese men reported PE, with similar prevalence of lifelong (3.18%), acquired (4.84%), variable PE (11.38%), and subjective

Rationale for ISSM Definition of Lifelong and Acquired Premature Ejaculation. The multivariate ISSM evidence-based definition of PE captures the key PE constructs of ejaculatory latency, perceived (ejaculatory control), and presence of negative personal consequences from PE (McMahon et al, 2008b). Although men with lifelong and acquired PE appear to share the dimensions of short ejaculatory latency, reduced or absent perceived ejaculatory control, and the presence of negative personal consequences from PE, they remain distinct and different demographic and etiologic populations (Porst and McMahon, 2010).

Rationale for Inclusion of “ejaculation always or nearly always occurs before or within approximately 1 minute of vaginal penetration IELT less than approximately 1 minute (lifelong PE) or a clinically significant and bothersome reduction in latency time, often to approximately 3 minutes or less (acquired PE).” Operationalization of PE using the length of time between penetration and ejaculation, the IELT, forms the basis of most current clinical studies on PE (Waldinger et al, 1994). IELT can be measured by a stopwatch or estimated. Several authors report that estimated and stopwatch IELT correlate reasonably well or are interchangeable in assigning PE status when estimated IELT is combined with PROs (Althof et al, 1995; Pryor, 2005; Rosen et al, 2007).

Several studies suggest that 80% to 90% of men seeking treatment for lifelong PE ejaculate within 1 minute (Waldinger et al, 1998, 2007; McMahon, 2002). Waldinger and colleagues (1998) reported IELTs of less than 30 seconds in 77% and less than 60 seconds in 90% of 110 men with lifelong PE, with only 10% ejaculating between 1 and 2 minutes. These data are consistent with normative community IELT data, support the notion that IELTs of less than 1 minute are statistically abnormal, and confirm that an IELT cutoff of 1 minute will capture 80% to 90% of treatment-seeking men with lifelong PE (Waldinger et al, 2005a). Further qualification of this cutoff to “approximately 1 minute” affords the clinician sufficient flexibility to also diagnose PE in the 10% to 20% of PE treatment-seeking men who ejaculate within 1 to 2 minutes of penetration without unnecessarily stigmatizing the remaining 80% to 90% of men who ejaculate within 1 to 2 minutes of penetration but have no reports of PE.

Porst and associates (2010) reported that both the arithmetic (1.1 vs. 0.9 min, $P < 0.001$) and geometric mean IELT (0.9 vs. 0.7 min, $P < .001$) were slightly (but significantly) greater for patients with acquired PE. Several authors confirmed this preliminary finding by demonstrating that self-estimated IELT is higher in men with acquired PE than in those with lifelong PE.

However, a post hoc analysis of the dapoxetine phase 3 COUPLE trial data confirms a statistically significant higher IELT in men with acquired PE and comorbidity compared to men with lifelong PE with comorbid ED (52.2 years vs. 45.5 years) (McMahon et al, 2013). Serefoglu and coworkers (2010) reported that self-estimated IELT was lowest in men with lifelong PE and highest in men with subjective PE (lifelong PE: 20.47 ± 28.90 seconds (2 to 120 seconds); acquired PE: 57.91 ± 38.72 seconds (90 to 180 seconds); variable PE: 144.17 ± 22.47 seconds (120 to 180 seconds); subjective PE: 286.67 ± 69.96 seconds (180 to 420 seconds, $P = .001$). Gao and associates (2013) and Zhang and colleagues (2013) confirmed that self-estimated IELT follows a continuum among the four PE syndromes and reported a mean self-estimated IELT of 1.65 ± 0.82 minutes and 1.84 ± 1.02 minutes, respectively, in patients with acquired PE. These data suggest 3 minutes as a valid cutoff for either self-estimated or stopwatch IELT for the diagnosis of acquired PE.

Rationale for Inclusion of “the inability to delay ejaculation on all or nearly all vaginal penetrations.” The ability to prolong sexual intercourse by delaying ejaculation and the subjective feelings of ejaculatory control make up the complex construct of ejaculatory control. Virtually all men report using at least one cognitive or behavioral technique to prolong intercourse and delay ejaculation, with varying degrees of success, and many young men reported using multiple different techniques (Grenier and Byers, 1997). Voluntary delay of ejaculation is most likely exerted either before or in the early stages of the emission phase of the reflex but

progressively decreases until the point of ejaculatory inevitability (McMahon et al, 2006b; Perelman, 2006).

Several authors suggest that an inability to voluntarily defer ejaculation defines PE (Kaplan et al, 1974; Zilbergeld, 1978; Vandereycken, 1986; McCarthy, 1988). Patrick and associates (2005) reported ratings of “very poor” or “poor” for control over ejaculation in 72% of men with PE, compared to 5% in a group of normal controls. Lower ratings for control over ejaculation were associated with shorter IELT with “poor” or “very poor” control reported by 67.7%, 10.2%, and 6.7% of subjects with IELT less than 1 minute, longer than 1 minute, and longer than 2 minutes, respectively. However, Grenier and Byers (1997, 2001) failed to demonstrate a strong correlation between ejaculatory latency and subjective ejaculatory control. Several authors report that diminished control is not exclusive to men with PE and that some men with a brief IELT report adequate ejaculatory control and vice versa, suggesting that the dimensions of ejaculatory control and latency are distinct concepts (Grenier and Byers, 1997; McMahon et al, 2005; Patrick et al, 2005). Furthermore, a greater variability exists in changes in control compared to IELT in men treated with selective serotonin reuptake inhibitors (SSRIs) (Waldinger et al, 2004a). Contrary to this, several authors report a moderate correlation between the IELT and the feeling of ejaculatory control (Rowland et al, 2000; Patrick et al, 2005; Rosen et al, 2007; Giuliano et al, 2008). Rosen and colleagues (2007) report that control over ejaculation, personal distress, and partner distress were more influential in determining PE status than IELT. In addition, the effect of IELT on satisfaction and distress appears to be mediated by its direct effect on control (Patrick et al, 2007). However, despite conflicting data on the relationship between control and latency, the balance of evidence supports the notion that the inability to delay ejaculation appears to differentiate men with PE from men without PE (Rowland et al, 2004a; Patrick et al, 2005; Giuliano et al, 2008).

Consistent with these findings, several recent studies report that the majority of patients with acquired and lifelong PE, regardless of comorbid ED, reported perceived control over ejaculation as “poor” or “very poor” (Porst et al, 2010; McMahon et al, 2013).

Rationale for Inclusion of “negative personal consequences, such as distress, bother, frustration, and/or the avoidance of sexual intimacy.” Several authors have reported an association between lifelong or acquired PE and negative psychological outcomes in men with lifelong or acquired PE and their female partners (McCabe, 1997; Dunn et al, 1999; Byers and Grenier, 2003; Symonds et al, 2003; Rowland et al, 2004a; Hartmann and colleagues, 2005; Patrick et al, 2005; Riley and Riley, 2005; Althof, 2006a, 2006b; Brock et al, 2007; Porst et al, 2007; Rowland et al, 2007; Giuliano et al, 2008; Rosen and Althof, 2008; McMahon et al, 2013). Patrick and colleagues (2005) reported significant differences in men with and without PE in the PRO measures of personal distress (64% vs. 4%) and interpersonal difficulty (31% vs. 1%), suggesting that this personal distress has discriminative validity in diagnosing men with and without PE. The personal and/or interpersonal distress, bother, frustration, and annoyance that result from PE may affect men’s quality of life and partner relationships, have an impact on their self-esteem and self-confidence, and can act as an obstacle to single men forming new partner relationships (McCabe, 1997; Dunn et al, 1999; Byers and Grenier, 2003; Symonds et al, 2003; Rowland et al, 2004a, 2007; Hartmann et al, 2005; Patrick et al, 2005; Riley and Riley, 2005; Althof, 2006a, 2006b; Brock et al, 2007; Porst et al, 2007; Giuliano et al, 2008; Rosen and Althof, 2008). McCabe (1997) reported that sexually dysfunctional men, including men with PE, scored lower on all aspects of intimacy (emotional, social, sexual, recreational, and intellectual) and had lower levels of satisfaction compared to sexually functional men ($P < .001$ or $P < .01$). Rowland and colleagues (2007) showed that men with PE had significantly lower overall health-related quality of life and total Self-Esteem and Relationship Questionnaire (SEAR) scores and lower confidence and self-esteem compared to non-PE groups. Men with PE rated their overall health-related quality of life lower than men without PE ($P \leq .001$).

Rationale for Exclusion of Sexual Satisfaction

Men with PE report lower levels of sexual satisfaction than men with normal ejaculatory latency (McCabe, 1997; Dunn et al, 1999; Byers and Grenier, 2003; Symonds et al, 2003; Rowland et al, 2004a; Hartmann et al, 2005; Patrick et al, 2005; Riley and Riley, 2005; Althof, 2006a, 2006b; Brock et al, 2007; Porst et al, 2007; Rowland et al, 2007; Giuliano et al, 2008; Rosen and Althof, 2008; Porst et al, 2010; McMahon et al, 2013). Patrick and coworkers (2005) reported ratings of “very poor” or “poor” for sexual satisfaction in 31% of subjects with PE compared to 1% in a group of normal controls. However, caution should be exercised in

assigning lower levels of sexual satisfaction solely to the effect of PE and contributions from other difficult-to-quantify issues such as reduced intimacy, dysfunctional relationships, poor sexual attraction, and poor communication should not be ignored. This is supported by the report of Patrick and colleagues (2005) that despite reduced ratings for satisfaction, with shorter IELTs, a substantial proportion of men with an IELT of less than 1 minute report “good” or “very good” satisfaction ratings (43.7%). The current data are limited but suggest that sexual satisfaction is of limited use in differentiating individuals with PE from those without PE and was not included in the ISSM definition of PE (Patrick et al, 2005).

Figure 29-2. Distribution of intravaginal ejaculatory latency times (IELT) values in a random cohort of 491 men. (From Waldinger M, Quinn P, Dilleen M, et al. A multinational population survey of intravaginal ejaculation latency time. *J Sex Med* 2005;2:492–7.)

PE (6.4%). Of particular interest is the report of [Serefoglu and colleagues \(2011\)](#) that men with acquired PE are more likely to seek medical treatment than men with lifelong PE (26.53% vs. 12.77%). This finding was confirmed by [Gao and coworkers \(2013\)](#), who demonstrated that patients with acquired PE were more likely to seek (17.12% vs. 14.58%) and plan to seek (36.30% vs. 27.08%) treatment for their PE than men with lifelong PE. These data suggest that the prevalence of acquired PE in the community is approximately 4% among sexually active adults and that these patients are more likely to seek medical treatment.

Causes of Premature Ejaculation

Historically, attempts to explain the cause of PE have included a diverse range of biologic and psychological theories. Most of these proposed causes are not evidence based and are speculative at best. Although men with lifelong and acquired PE appear to share the dimensions of short ejaculatory latency, reduced or absent perceived ejaculatory control, and presence of negative personal consequences from PE, they remain distinct and different demographic and etiologic populations ([Porst et al, 2010](#)).

Lifelong Premature Ejaculation

[Waldinger and colleagues \(1998\)](#) hypothesized that lifelong early ejaculation in humans may be explained by either a hyposensitivity of the 5-HT_{2C} and/or hypersensitivity of the 5-HT_{1A} receptor. Recent studies suggest that in some men, neurobiologic and genetic variations could contribute to the pathophysiology of lifelong PE, as defined by the ISSM criteria and that the condition may be maintained and heightened by psychological/environmental factors ([Janssen et al, 2009](#)).

Acquired Premature Ejaculation

Acquired PE is commonly due to sexual performance anxiety ([Hartmann et al, 2005](#)), psychological or relationship problems ([Hartmann et al, 2005](#)), ED ([Laumann et al, 2005](#)), occasionally prostatitis ([Screponi et al, 2001](#)), or hyperthyroidism ([Carani et al, 2005](#)) or during withdrawal/detoxification from prescribed ([Adson and Kotlyar, 2003](#)) or recreational ([Peugh and Belenko, 2001](#)) drugs. Consistent with the predominant organic cause of acquired

PE, men with this problem are usually older, have a higher mean body mass index (BMI), and have a greater incidence of comorbid disease, including hypertension, sexual desire disorder, diabetes mellitus, chronic prostatitis, and ED, than men with lifelong, variable, and subjective PE ([Basile Fasolo et al, 2005](#); [Porst et al, 2010](#); [Serefoglu et al, 2010](#); [Serefoglu et al, 2011](#); [Gao et al, 2013](#); [McMahon et al, 2013](#); [Zhang et al, 2013](#)).

Premature Ejaculation and Sexual Performance Anxiety, Psychological Problems, and Relationship Problems

Anxiety has been reported as a cause of PE by multiple authors and is entrenched in the folklore of sexual medicine as the most likely cause of PE despite scant empirical research evidence to support any causal role ([Jern et al, 2007](#); [Janssen et al, 2009](#)). Several authors suggest that anxiety activates the sympathetic nervous system and reduces the ejaculatory threshold as a result of an earlier emission phase of ejaculation ([Janssen et al, 2009](#)).

Hypoactive sexual desire may lead to PE, as a result of an unconscious desire to abbreviate unwanted penetration. Similarly, diminished sexual desire can be a consequence of chronic and frustrating PE.

Female sexual dysfunctions (such as anorgasmia, hypoactive sexual desire, sexual aversion, sexual arousal disorders, and sexual pain disorders, such as vaginismus ([Dogan and Dogan, 2008](#))) also may be related to acquired PE.

Premature Ejaculation and Comorbid Erectile Dysfunction

Recent data demonstrate that as many as half of subjects with ED also experience PE ([Basile Fasolo et al, 2005](#); [Laumann et al, 2005](#); [Porst et al, 2007](#)).

Premature Ejaculation and Prostate Disease

Acute and chronic lower urogenital infection, prostatodynia, or chronic pelvic pain syndrome (CPPS) is associated with ED, PE, and painful ejaculation ([Waldinger et al, 2005c](#); [Donatucci, 2006](#); [Zohdy, 2009](#); [Rowland et al, 2010](#)). Several studies report PE as the main sexual disorder symptom in men with chronic prostatitis or CPPS, with a prevalence of 26% to 77% ([Rowland et al,](#)

2010). The exact pathophysiology of the links among chronic prostatitis, ED, and PE is unknown. It has been hypothesized that prostatic inflammation may result in altered sensation and modulation of the ejaculatory reflex, but evidence is lacking (Donatucci, 2006; Shamloul and El-Nashaar, 2006; Sharlip, 2006). It has been reported that antibiotic treatment of microbiologically confirmed bacterial prostatitis in men with acquired PE resulted in a 2.6-fold increase in IELT and improved ejaculatory control in 83.9% of subjects (El-Nashaar and Shamloul, 2007).

Premature Ejaculation and Hyperthyroidism

The majority of patients with thyroid hormone disorders experience sexual dysfunction. Studies suggest a significant correlation between PE and suppressed thyroid-stimulating hormone (TSH) values in a selected population of andrologic and sexologic patients. The 50% prevalence of PE in men with hyperthyroidism fell to 15% after treatment with thyroid hormone normalization (Carani et al, 2005). Although occult thyroid disease has been reported in the elderly hospitalized population, it is uncommon in the population who present for treatment of PE and routine TSH screening is not necessary unless clinically indicated (Atkinson et al, 1978).

Evaluation of Men Reporting Premature Ejaculation

Medical History

Men presenting with self-reported PE should be evaluated with a full medical and sexual history, a focused physical examination, inventory assessment of erectile function, and any investigations suggested by these findings. Inclusion of the partner in the management process is an important but not mandatory ingredient for treatment success. Some patients may not understand why the clinician wishes to include the partner, and some partners may be reluctant to join the patient in treatment. However, if partners are not involved in treatment, they may be resistant to changing the sexual interaction (Donahey and Miller, 2000). A cooperative partner can enhance the man's self-confidence, skills, self-esteem, and sense of masculinity and more generally assist the man to develop ejaculatory control (Perelman, 2003). This is in turn likely to lead to an improvement in the couple's sexual relationship, as well as the broader aspects of their relationship. No controlled studies have been done on the impact of involving partners in treating PE. However, a review of treatment studies for ED demonstrated the important role of including a focus on interpersonal factors on treatment success (Mohr and Bentler, 1990).

Patients expect clinicians to inquire about their sexual health (Schein et al, 1988). Often patients are too embarrassed, shy, and uncertain if sexual complaints belong in the health care professional's office (Humphrey and Nazareth, 2001). Inquiry into sexual health gives patients permission to discuss their sexual concerns and also screens for associated health risks (e.g., cardiovascular risk and ED). Box 29-1 lists recommended and optional questions that patients who report PE should be asked (McMahon et al, 2004b; Althof et al, 2010). The recommended questions establish the diagnosis and direct treatment considerations and the optional questions gather detail for implementing treatment. Finally, the committee recommends that the health care providers take a medical and psychosocial history.

Diagnosis of Premature Ejaculation

The ISSM definition of PE should form the basis for the diagnosis of PE. A significant population of men with self-reported PE fails to satisfy the criteria of the ISSM definition of PE. This parallels the substantial disparity between the self-reported incidence of PE in epidemiologic studies (Laumann et al, 1999) and that suggested by community-based normative stopwatch IELT studies (Waldinger et al, 2005a). This population has recently been categorized as having either variable PE or subjective PE (Waldinger et al, 2006b;

BOX 29-1 Recommended and Optional Questions to Establish the Diagnosis of Premature Ejaculation (PE) and Direct Treatment

RECOMMENDED QUESTIONS FOR DIAGNOSIS OF PE

What is the time between penetration and ejaculation (coming)?
Can you delay ejaculation?
Do you feel bothered, annoyed, and/or frustrated by your PE?

OPTIONAL QUESTIONS

Differentiate Lifelong and Acquired PE

When did you first experience PE?
Have you experienced PE since your first sexual experience on every/almost every attempt and with every partner?

Assess Erectile Function

Is your erection hard enough to penetrate?
Do you have difficulty in maintaining your erection until you ejaculate during intercourse?
Do you ever rush intercourse to prevent loss of your erection?

Assess Relationship Impact

How upset is your partner with your PE?
Does your partner avoid sexual intercourse?
Is your PE affecting your overall relationship?

Previous Treatment

Have you received any treatment for your PE previously?

Impact on Quality of Life

Do you avoid sexual intercourse because of embarrassment?
Do you feel anxious, depressed, or embarrassed because of your PE?

From Althof SE, Abdo CH, Dean J, et al. International Society for Sexual Medicine's guidelines for the diagnosis and treatment of premature ejaculation. *J Sex Med* 2010;7:2947–69.

Waldinger and Schweitzer, 2008). Men with subjective PE report PE but have a normal ejaculatory latency typically of 2 to 6 minutes but on some occasions as long as 25 minutes. It is characterized by a preoccupation with a subjective but false perception of PE with an ejaculation latency time (ELT) within the normal range but often with reduced ejaculatory control.

Determination of Intravaginal Ejaculation Latency Time

Self-estimation by the patient and partner of IELT should be used to determine IELT in clinical practice. Stopwatch measures of IELT are widely used in clinical trials and observational studies of PE, but have not been recommended for use in routine clinical management of PE. Despite the potential advantage of objective measurement, stopwatch measures have the disadvantage of being intrusive and potentially disruptive of sexual pleasure or spontaneity. More recently, studies have indicated that patient or partner self-report of ejaculatory latency correlate relatively well with objective stopwatch latency and might be useful as a proxy measure of IELT (Althof, 1998; Pryor et al, 2005; Rosen et al, 2007; McMahon, 2008a). Because patient self-report is the determining factor in treatment seeking and satisfaction, it is recommended that self-estimation by the patient and partner of ejaculatory latency be accepted as the method for determining IELT in clinical practice.

Patient-Reported Outcome Measures

Standardized assessment measures such as validated questionnaires and PRO measures can be used as an adjunct to a full medical and sexual history and self-estimation of ejaculatory latency in the evaluation of men presenting with self-reported PE. These measures are all relatively new and were developed primarily for use as research tools. Some have shown good psychometric properties and are potentially valuable adjuncts for clinical screening and assessment.

Several PE measures have been described in the literature (Yuan et al, 2004; Althof et al, 2006; Arafa and Shamloul, 2007; Symonds et al, 2007a, 2007b; Patrick et al, 2008; Serefoglu et al, 2009), although only a small number have undergone extensive psychometric testing and validation. Five validated questionnaires have been developed and published to date. Currently, two questionnaires have extensive databases and meet most of the criteria for test development and validation: the **Premature Ejaculation Profile (PEP)** and the **Index of Premature Ejaculation (IPE)** (Althof et al, 2006; Patrick et al, 2008). A third brief diagnostic measure, the **Premature Ejaculation Diagnostic Tool (PEDT)**, has a modest database and is available for clinical use (Symonds et al, 2007a). Two other measures, the Arabic and Chinese PE Questionnaires, have minimal validation or clinical trial data available and are not recommended for clinical use.

Further details of PRO measures are available on the Expert Consult website.

Assessment of Erectile Function

The presence of comorbid ED should be evaluated using a validated instrument such as the **International Index of Erectile Function (IIEF)** or the **IIEF-5 (SHIM)**. Normal erectile function should be defined as an **IIEF Erectile Function Domain** of 26 or greater or **IIEF-5** greater than 21 (Rosen et al, 1997; Cappelleri et al, 2001). Recent data demonstrate that as many as half of subjects with ED also experience PE (Jannini et al, 2005). In the European Premature Ejaculation Study (PEPA), ED was present in 31.9% of men with PE compared to 11.8% of men without PE (Porst et al, 2007). In the GSSAB, the odds ratio for ED in men with PE ranged from 6.0 in Europe and as high as 11.9 in South America (Laumann et al, 2005). Consistent with this, ED is more prevalent in men with acquired PE than lifelong PE (Basile Fasolo et al, 2005). PE is also more common with increasing severity of ED after adjustment for age (Corona et al, 2004; El-Sakka, 2006, 2008). Men with ED may either require higher levels of stimulation to achieve an erection or intentionally “rush” intercourse to prevent early detumescence of a partial erection, resulting in ejaculation with a brief latency (Jannini et al, 2005). This may be compounded by the presence of high levels of performance anxiety related to their ED, which serves to only worsen their prematurity. However, caution should be exercised in the diagnosis of comorbid ED in men with PE, because 33.3% of potent men with PE confuse the ability to maintain erections before and after ejaculation, record contradictory response/s to some/all questions of the SHIM, especially Q3 and Q4, and receive a false-positive SHIM diagnosis of ED (McMahon, 2009).

Physical Examination

Current literature suggests that the diagnosis of lifelong PE is based purely on the medical history because there are no predictive physical findings or confirmatory investigations (McMahon, 2005). As differentiation of lifelong PE and acquired PE may be difficult in either young men or men with no or few previous sexual partners and/or limited sexual experience, a physical examination is highly desirable and represents an opportunity for screening for cardiovascular or gender-specific diseases. However, in men with acquired PE, a physical examination is mandatory in an effort to identify the cause of the PE and to alleviate its possible cause (Jannini et al, 2006b). The presence of ED should be evaluated either by medical history or with the assistance of a validated instrument. Laboratory

or imaging investigations are occasionally required based on the patient's medical history. A digital prostate examination, routine in an andrologic setting for all men over 40, is useful in identifying possible evidence of prostatic inflammation or infection (Jannini et al, 2006a).

Treatment of Premature Ejaculation

Figure 29-3 is a flow chart for the management of PE (Rowland et al, 2010). **Multiple psychosexual and pharmacologic treatments are available for PE.** Men with lifelong PE are best managed with PE pharmacotherapy alone or in combination with graded levels of patient and couple psychosexual therapy. Men with acquired PE should receive cause-specific treatment (e.g., psychosexual counseling or ED pharmacotherapy, alone or in combination with PE pharmacotherapy). Men with natural variable PE or PE-like ejaculatory dysfunction should be primarily treated with psychosexual education and graded patient and couple psychotherapy.

Psychosexual Therapy

All men seeking treatment for PE should receive basic psychosexual education or coaching (Althof, 2006c, 2007; Perelman, 2003, 2006). This may include providing information on the prevalence of PE and general population IELT to dispel myths about PE, information on enjoyable sexual activities to extend the man and his partner's sexual repertoire, as well as strategies to address avoidance of sexual activity or unwillingness to discuss sex with his partner. These educational strategies are designed to give the man the confidence to try the medical intervention, reduce performance anxiety, and modify his maladaptive sexual scripts.

Additional information on the role of psychosexual therapy in the management of PE is available on the Expert Consult website.

Pharmacologic Treatment

Several forms of pharmacotherapy have been used in the treatment of PE (Giuliano and Clement, 2012). These include the use of **topical local anesthetics, SSRIs, tramadol, phosphodiesterase type 5 (PDE5) inhibitors, and α -adrenergic blockers**. The use of topical local anesthetics, such as lidocaine, prilocaine, or benzocaine, alone or in association, to diminish the sensitivity of the glans penis is the oldest known pharmacologic treatment for PE (Schapiro, 1943). The introduction of the SSRIs paroxetine, sertraline, fluoxetine, and citalopram and the tricyclic antidepressant (TCA) clomipramine has revolutionized the treatment of PE. These drugs block axonal reuptake of serotonin from the synaptic cleft of central serotonergic neurons by 5-HT transporters, resulting in enhanced 5-HT neurotransmission and stimulation of postsynaptic membrane 5-HT receptors.

Treatment with Selective Serotonin Reuptake Inhibitors and Tricyclic Antidepressants. PE can be treated with on-demand SSRIs such as dapoxetine or off-label clomipramine, paroxetine, sertraline, and fluoxetine or with daily dosing of off-label paroxetine, clomipramine, sertraline, fluoxetine, or citalopram.

Dapoxetine. Dapoxetine has received approval for the treatment of PE in over 50 countries worldwide. Dapoxetine has not received marketing approval for the United States by the U.S. Food and Drug Administration. It is a rapid-acting and short-half-life SSRI with a pharmacokinetic profile supporting a role as an on-demand treatment for PE (Pryor et al, 2006). No drug-drug interactions associated with dapoxetine, including phosphodiesterase inhibitor drugs, have been reported. In randomized controlled trials (RCTs), dapoxetine 30 mg or 60 mg taken 1 to 2 hours before intercourse is more effective than placebo from the first dose, resulting in 2.5- and 3.0-fold increases in IELT, increased ejaculatory control, decreased distress, and increased satisfaction. Dapoxetine was comparably effective in men with lifelong and acquired PE (Porst et al, 2010) and was similarly effective and well tolerated in men with PE and comorbid ED treated with PDE5 inhibitor drugs (McMahon et al, 2013). Treatment-related side effects were

Premature Ejaculation Profile

A four-item, self-report measure of PE has been developed by Patrick and colleagues (2008). The PEP comprises single-item constructs of (1) perceived control over ejaculation, (2) satisfaction with sexual intercourse, (3) personal distress related to ejaculation, (4) interpersonal difficulty related to ejaculation, and (5) an index or total score. Each of the four individual items is assessed on a 5-point scale, which are averaged to provide an index PE score. The measure has been used in observational studies and clinical trials of PE (Patrick et al, 2005). It also has been recommended for clinical use in evaluating the subjective components of the disorder. Validation studies have been performed in comparison to stopwatch measures of intravaginal latency and other PRO measures of sexual function and distress (Patrick et al, 2005, 2008). The scale has adequate test-retest reliability (total scale = 0.80) and moderate to strong correlations with stopwatch-measured IELT. A major limitation of the scale is the lack of validated cutoff scores, which make it less suitable for use as a diagnostic or clinical screening tool. On the positive side, it is very brief and easy to administer and may be valuable for use in a clinical setting as a measure of treatment responsiveness.

Index of Premature Ejaculation

The IPE was developed by Althof and colleagues (2006). It is a 10-item self-administered questionnaire designed to evaluate sexual satisfaction, control, and distress in men with PE. It was developed using four stages: item pool development, initial psychometric

analyses, patient interviews, and final psychometric analyses. The IPE contains three factor analytically derived domains: control, sexual satisfaction, and distress. All three domains have shown adequate internal consistency and reliability, as well as known group validity in comparing men with and without PE. Convergent validity against IELT was also strong for all three domains (control [$r = .75$], sexual satisfaction [$r = .60$], and distress [$r = .68$]).

The IPE has the advantages of also being relatively brief and easy to administer, although the measure is not as brief as the PEP. It also assesses clinically relevant domains and has adequate known group validity data. However, similar to the PEP, it lacks norms and diagnostic cutoffs and has limited value as a diagnostic or screening measure for PE.

Premature Ejaculation Diagnostic Tool

The two measures (PEP, IPE) discussed previously are available for use as treatment change or outcome measures of PE treatment. The PEDT, in contrast, was developed specifically for use as a screening questionnaire (Symonds et al, 2007a, 2007b; Serefoglu et al, 2009). This questionnaire is a brief, 5-item measure used to screen men for potential presence of PE based on DSM-IV-TR criteria of lack of control, frequency, minimal stimulation, distress, and interpersonal difficulty.

Depending on the specific need, the PEP and IPE are currently the preferred questionnaire measures for assessing PE, particularly when monitoring responsiveness to treatment. Overall, these measures may serve as useful adjuncts, but should not substitute for a detailed sexual history performed by a qualified clinician.

Graded levels of patient and couple counseling, guidance, and/or relationship therapy, either alone or ideally in combination with PE pharmacotherapy, should be offered as a treatment option for most men with PE. PE exerts a significant psychological burden on men, their partners, the male/partner relationship, and their overall relationship (Rust et al, 1988; Symonds et al, 2003). Men with PE show other negative effects, including a general negative affect associated with sexual situations, as well as more intense feelings of embarrassment/guilt, worry/tension, and fear of failure (Sotomayor, 2005). These individuals indicate decreased self-confidence, increased distress and interpersonal difficulty, and mental preoccupation with their condition (Hartmann et al, 2005; Patrick et al, 2005). Partner satisfaction may play a greater role in PE than ED, so it is not surprising that relationship dysfunction is reported as the second most common negative effect of PE (Hartmann et al, 2005; Symonds et al, 2003). Not only is PE associated with marital discord (Rust et al, 1988), but the insecurity of men with PE about satisfying the partner also serves as an obstacle to initiating and maintaining new relationships (Symonds et al, 2003; Sotomayor, 2005).

Until recently, treatment options have been limited to behavioral and psychological procedures. Psychological factors such as anxiety and negative affect have frequently been associated with sexual dysfunctions such as PE (Kaplan, 1983, 1989), and treatment addressing such issues has represented a logical approach. Psychological-behavioral strategies for treating PE have been at least moderately successful in alleviating the dysfunction in the short term (Golden et al, 1978; De Amicis et al, 1984; Hawton et al, 1986; Levine, 1992; de Carufel and Trudel, 2006).

Psychological interventions are designed to achieve more than simply increasing the IELT. Targeted factors focus on the man, his partner, and their relationship. Psychotherapy and behavioral interventions improve ejaculatory control by helping men/couples to (1) learn techniques to control and/or delay ejaculation, (2) gain confidence in their sexual performance, (3) lessen performance anxiety, (4) modify rigid sexual repertoires, (5) surmount barriers to intimacy, (6) resolve interpersonal issues that precipitate and maintain the dysfunction, (7) increase communication (Althof, 2003; Althof

and Wieder, 2004), and (8) come to terms with feelings/thoughts that interfere with sexual function.

Present-day psychotherapy for PE most often represents an integration of behavioral (e.g., the well-known start-stop and pause-squeeze methods) and cognitive approaches within a short-term psychotherapy model (Golden et al, 1978; De Amicis et al, 1984; Hawton et al, 1986; Levine, 1992; Althof and Wieder, 2004; de Carufel and Trudel, 2006). The guiding principles of treatment are to learn to control ejaculation while understanding the meaning of the symptom and the context in which it occurs.

Although the new and often more expedient pharmacologic therapies are overshadowing traditional psychological-behavioral methods in the treatment of PE, the psychological-behavioral approach remains an attractive option for several reasons. The treatment is specific to the problem; is neither harmful nor painful; depends less on the man's medical history; produces minimal or no adverse side effects; and encourages open communication about sexuality in the couple, which is likely to lead to a more satisfying sexual relationship (Verhulst and Heiman, 1988; Wincze and Carey, 1991). Once the techniques have been learned and incorporated into lovemaking, men with PE continue to have access to strategies that help them control their ejaculation. At the same time, there are drawbacks to the psychological-behavioral approach: it is time-consuming, often requires substantial resources of both time and money, lacks immediacy, requires the partner's cooperation, and has mixed (and less well-documented) efficacy. Furthermore, data to support long-term efficacy are lacking.

Combining a medical and psychological approach may be especially useful in men with acquired PE in whom there is a clear psychosocial precipitant or lifelong if the individual or couple's responses to PE are likely to interfere in the medical treatment and ultimate success of therapy. Similarly, in men with PE and comorbid ED, combination therapy also may be helpful to manage the psychosocial aspects of these sexual dysfunctions. Once the man's self-confidence and sense of control have improved, it may then be possible to reduce or discontinue the medical intervention (McMahon, 2002).

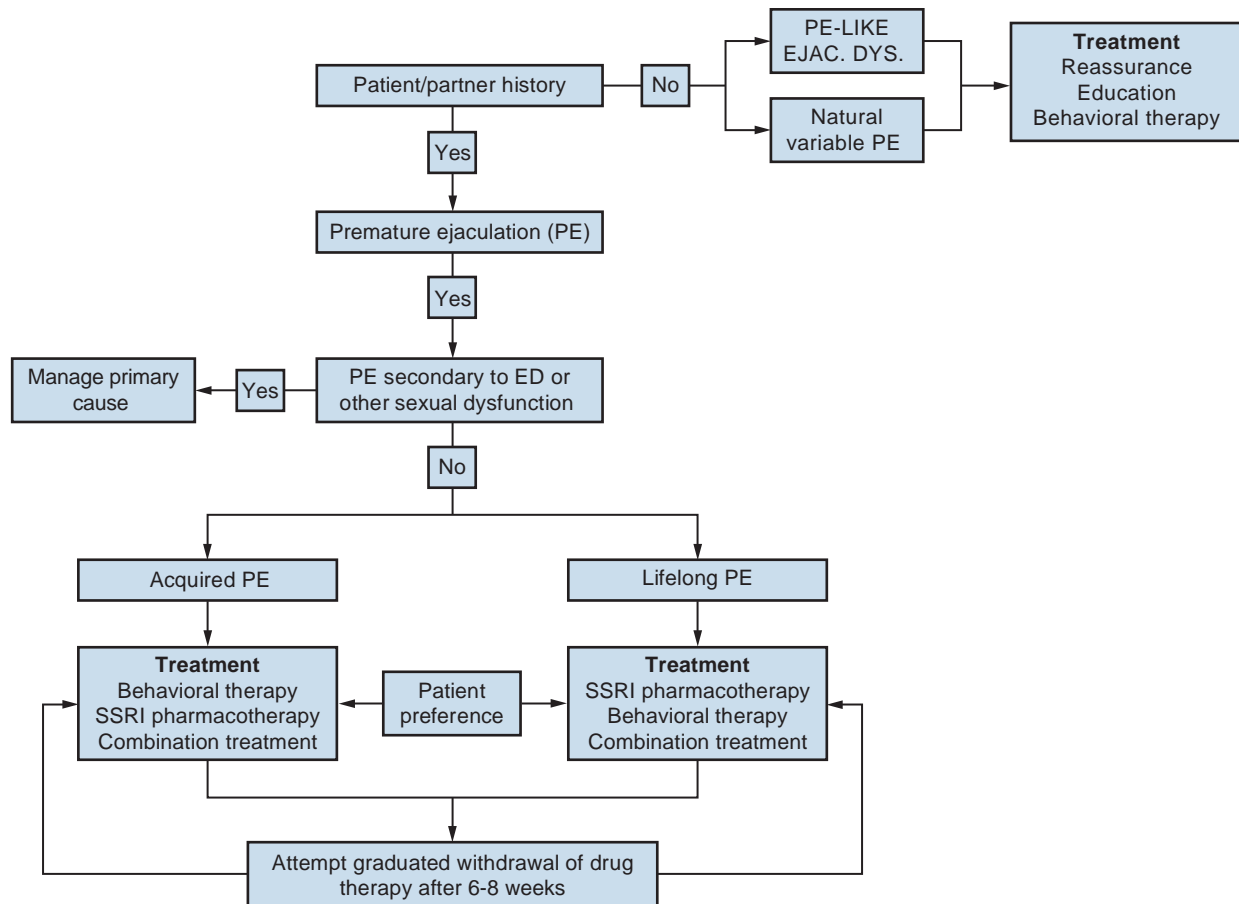

Figure 29-3. Algorithm for the office management of premature ejaculation (PE). ED, erectile dysfunction; EJAC. DYS., ejaculation dysfunction; SSRI, selective serotonin reuptake inhibitor.

uncommon and dose dependent and included nausea, diarrhea, headache, and dizziness (McMahon et al, 2011). They were responsible for study discontinuation in 4% (30 mg) and 10% (60 mg) of subjects. There was no indication of an increased risk for suicidal ideation or suicide attempts and little indication of withdrawal symptoms with abrupt dapoxetine cessation (Levine, 2006).

Off-Label Selective Serotonin Reuptake Inhibitors and Tricyclic Antidepressants. Daily treatment with off-label paroxetine 10 to 40 mg, clomipramine 12.5 to 50 mg, sertraline 50 to 200 mg, fluoxetine 20 to 40 mg, and citalopram 20 to 40 mg is usually effective in delaying ejaculation. A meta-analysis of published data suggests that paroxetine exerts the strongest ejaculation delay, increasing IELT approximately 8.8-fold over baseline (Waldinger et al, 2004b).

Ejaculation delay usually occurs within 5 to 10 days of starting treatment, but the full therapeutic effect may require 2 to 3 weeks of treatment and usually is sustained during long-term use (McMahon, 2002). Adverse effects are usually minor, start in the first week of treatment, and may gradually disappear within 2 to 3 weeks. They include fatigue, yawning, mild nausea, diarrhea, or perspiration. Anecdotal reports show that decreased libido and ED are less frequently seen in nondepressed men with PE treated by SSRIs compared to depressed men treated with SSRIs (Waldinger, 2007). Neurocognitive adverse effects include significant agitation and hypomania in a small number of patients, and treatment with SSRIs should be avoided in men with a history of bipolar depression (Marangell et al, 2008).

Platelet serotonin release has an important role in hemostasis (Li et al, 1997) and SSRIs, especially with concurrent use of aspirin and nonsteroidal anti-inflammatory drugs, may be associated with

increased risk for upper gastrointestinal bleeding. Priapism is a rare adverse effect of SSRIs and requires urgent medical treatment. Long-term SSRI use may be associated with weight gain and an increased risk for type 2 diabetes mellitus (Fava et al, 2000). In men with normal semen parameters, paroxetine has been reported to induce abnormal sperm DNA fragmentation in a significant proportion of subjects, without a measurable effect on semen parameters. The fertility potential of a substantial number of men on paroxetine may be adversely affected by these changes in sperm DNA integrity (Tanrikut et al, 2010).

Systematic analysis of RCTs of antidepressants (SSRIs and other drug classes) in patients with depressive and/or anxiety disorders indicates a small increase in the risk for suicidal ideation or suicide attempts in youth but not adults. In contrast, the risk for suicidal ideation has not been found in trials with SSRIs in nondepressed men with PE. Caution is suggested in prescribing SSRIs to young adolescents with PE aged 18 years or less, and to men with PE and a comorbid depressive disorder, particularly when associated with suicidal ideation (Khan et al, 2003). Patients should be advised to avoid sudden cessation or rapid dose reduction of daily dosed SSRIs, which may be associated with an SSRI withdrawal syndrome (Black et al, 2000).

On-demand administration of clomipramine, paroxetine, sertraline, and fluoxetine 3 to 6 hours before intercourse is modestly efficacious and well tolerated but is associated with substantially less ejaculatory delay than daily treatment in most studies (Kim and Paick, 1999; McMahon and Touma, 1999; Strassberg et al, 1999; Waldinger et al, 2004a). On-demand treatment may be combined with either an initial trial of daily treatment or concomitant low-dose daily treatment (McMahon and Touma, 1999).

Patients are often reluctant to begin off-label treatment of PE with SSRIs. [Salonia and associates \(2009\)](#) reported that 30% of patients refused to begin treatment (paroxetine 10 mg/day for 21 days followed by 20 mg as needed) and another 30% of those who began treatment discontinued it ([Salonia et al, 2009](#)). Similarly, [Mondaini and colleagues](#) reported that in a clinic population, 90% of patients either refused to begin or discontinued dapoxetine within 12 months of beginning treatment ([McMahon, 2002](#)). Reasons given included not wanting to take an antidepressant, treatment effects below expectations, and cost.

The decision to treat PE with either on-demand dosing of dapoxetine (where available) or daily dosing of off-label SSRIs should be based on the treating physician's assessment of individual patient requirements. Although many men with PE who engage in sexual intercourse infrequently may prefer on-demand treatment, many men in established relationships may prefer the convenience of daily medication. Well-designed preference trials will provide additional insight into the role of on-demand dosing. In some countries, off-label prescribing may present difficulties for the physician because the regulatory authorities strongly advise against prescribing for indications in which a medication is not licensed or approved. Obviously this complicates treatment in countries where there is no approved medication and the regulatory authorities advise against off-label prescription.

Off-Label Topical Local Anesthetics. The use of topical local anesthetics such as lidocaine and/or prilocaine as a cream, gel, or spray is well established and is moderately effective in delaying ejaculation. Data suggest that diminishing the glans sensitivity may inhibit the spinal reflex arc responsible for ejaculation ([Wieder et al, 2000](#)). [Dinsmore and associates \(2007\)](#) reported on the use of PSD502, a lidocaine-prilocaine spray currently in clinical trials that is applied to the penis at least 5 minutes before intercourse. The treated group reported a 6.3-fold increase in IELT and associated improvements in PRO measures of control and sexual satisfaction ([Dinsmore et al, 2007](#); [Henry et al, 2008](#)). Minimal reports have been made of penile hypoanesthesia and transfer to the partner as a result of the unique formulation of the compound. Other topical anesthetics are associated with significant penile hypoanesthesia and possible transvaginal absorption, resulting in vaginal numbness and resultant female anorgasmia unless a condom is used ([Busato and Galindo, 2004](#)).

Phosphodiesterase Type 5 Inhibitors. Off-label on-demand or daily dosing of PDE5 inhibitors is not recommended for the treatment of lifelong PE in men with normal erectile function. ED pharmacotherapy alone or in combination with PE pharmacotherapy is recommended for the treatment of lifelong PE or acquired PE in men with comorbid ED. PDE5 inhibitors sildenafil, tadalafil, and vardenafil are effective treatments for ED. Several authors have reported experience with PDE-5 inhibitors alone or in combination with SSRIs as a treatment for PE ([Abdel-Hamid et al, 2001](#); [Chia, 2002](#); [Erenpreiss and Zalkalns, 2002](#); [Linn et al, 2002](#); [Salonia et al, 2002](#); [Chen et al, 2003](#); [Li et al, 2003](#); [Lozano, 2003](#); [Tang et al, 2004](#); [Mattos and Lucon, 2005](#); [McMahon et al, 2005](#); [Sommer et al, 2005](#); [Zhang et al, 2005](#); [Atan et al, 2006](#); [Sun et al, 2007](#); [Mattos et al, 2008](#); [Aversa et al, 2009](#); [Mathers et al, 2009](#); [Jannini et al, 2011](#)). The putative role of PDE5 inhibitors as a treatment for PE is speculative and based only on the role of the nitric oxide (NO)/cyclic guanosine monophosphate (cGMP) transduction system as a central and peripheral mediator of inhibitory nonadrenergic, noncholinergic nitrergic neurotransmission in the urogenital system ([Mamas et al, 2003](#)). Although systematic reviews of studies on the PDE5 inhibitor drug treatment of PE have failed to provide robust empirical evidence to support a role of PDE5 inhibitors in the treatment of PE, with the exception of men with PE and comorbid ED ([McMahon et al, 2006a](#); [Asimakopoulos et al, 2012](#)), recent well-designed studies do support a potential role for these agents, suggesting a need for further evidence-based research ([Aversa et al, 2009](#)).

Some evidence supports the efficacy and safety of off-label, on-demand, or daily dosing of PDE5 inhibitors in the treatment of lifelong PE in men with normal erectile function (level of

evidence 4D). Treatment of lifelong PE with PDE5 inhibitors in men with normal erectile function is not recommended, and further evidence-based research is encouraged to understand conflicting data.

Table 29-2 is a summary of recommended pharmacologic treatments for PE.

Treatment of PE with tramadol, α_1 -adrenoceptor antagonists, intracavernous injection of vasoactive drugs, acupuncture, surgical neurotomy, cryoablation, and neuromodulation of the dorsal penile nerve is discussed in detail on the Expert Consult website.

Conclusion

Recent epidemiologic and observational research has provided new insights into PE and the associated negative psychosocial effects of this dysfunction. Recent normative data suggest that 80% to 90% of treatment-seeking men with lifelong PE will ejaculate within 1 minute and form the basis of the ISSM definition of lifelong. Although insufficient empirical evidence exists to clearly identify the cause of PE, limited evidence suggests that men with PE may have a genetic predisposition toward rapid ejaculation, high levels of sexual anxiety, and comorbid ED.

The use of dapoxetine and off-label SSRIs, clomipramine, and topical anesthetics has drawn new attention to this common and often ignored sexual problem. PE pharmacotherapy fails to directly completely address causal psychological or relationship factors, and data are either lacking or scarce on the efficacy of combined psychosexual counseling and pharmacologic treatment and the maintenance of improved ejaculatory control after drug withdrawal.

KEY POINTS: PREMATURE EJACULATION

- PE is a common sexual dysfunction.
- PE is associated with negative psychological consequences, including distress, bother, and frustration that may affect quality of life, partner relationships, self-esteem, and self-confidence and can act as an obstacle to single men forming new partner relationships.
- The evidence-based ISSM definition of lifelong and acquired PE should form the basis of the office diagnosis of lifelong PE.
- Limited evidence suggests lifelong PE has a genetic basis and acquired PE is most often the result of sexual performance anxiety, psychological or relationship problems, and/or ED.
- Oral SSRI drugs and topical anesthetic drugs are effective and safe treatments for PE.
- Psychosexual cognitive behavioral therapy has a limited role as a first-line treatment for PE but has an important role as an adjunct to pharmacotherapy, especially in men with acquired PE resulting from sexual performance anxiety.
- Men with acquired PE, most often secondary to comorbid ED, hyperthyroidism, chronic lower urogenital infection, prostatodynia, or CPPS, should receive appropriate cause-specific treatment alone or in combination with an SSRI.

DELAYED EJACULATION, ANEJACULATION, AND ANORGMASIA

Any psychological or medical disease or surgical procedure that interferes with either central control of ejaculation or the peripheral sympathetic nerve supply to the vas and bladder neck, the somatic efferent nerve supply to the pelvic floor, or the somatic afferent nerve supply to the penis can result in delayed ejaculation, anejaculation, retrograde ejaculation, and/or anorgasmia. Thus the

On-Demand Treatment with Off-Label Tramadol. Tramadol is a centrally acting synthetic opioid analgesic with an unclear mode of action that is thought to include binding of parent and M1 metabolite to μ -opioid receptors and weak inhibition of reuptake of GABA, norepinephrine, and serotonin (Frink et al, 1996). The efficacy of on-demand tramadol in the treatment of PE was recently reported (Salem et al, 2008; Alghobary et al, 2010; Xiong et al, 2011; Kaynar et al, 2012). Most studies are poorly designed open-label trials with a wide range of efficacy. The only double-blind, well-designed trial demonstrates a superiority to placebo but a mediocre-fold increase in IELT of 2.49, consistent with the weak serotonin reuptake inhibitor activity of tramadol (Bar-Or et al, 2012). The unclear safety profile and the potential for addiction discourage use of tramadol in PE clinical practice.

Tramadol may be an effective option for the treatment of PE. However, it may be considered when other therapies have failed because of the risk for addiction and side effects. It should *not* be combined with an SSRI because of the risk for serotonin syndrome, a potentially fatal outcome (Takeshita and Litzinger, 2009). Further well-controlled studies are required to assess the efficacy and safety of tramadol in the treatment of patients with PE (level of evidence 2).

Daily Treatment with Off-Label α_1 -Adrenoceptor Antagonists. Ejaculation is a sympathetic spinal cord reflex that could theoretically be delayed by α_1 -adrenergic blockers. Several researchers have reported their experience with the selective α_1 -adrenergic blockers alfuzosin and terazosin in the treatment of PE. Both drugs are approved only for the treatment of lower urinary tract symptoms (LUTS) in men with obstructive benign prostatic hyperplasia (BPH). In a double-blind placebo-controlled study, Cavallini (1995) reported that both alfuzosin (6 mg/day) and terazosin (5 mg/day) were effective in delaying ejaculation in approximately 50% of the cases. Similarly, Basar and colleagues (2005) reported that terazosin was effective in 67% of men. However, both studies were limited by the use of subjective study end points of patient impression of change and sexual satisfaction, and they did not evaluate actual ejaculatory latency. Additional controlled studies are required to determine the role of α_1 -blockers in the treatment of PE.

Intracavernous Injection of Off-Label Vasoactive Drugs. Intracavernous self-injection treatment of PE has been reported but is currently without any evidence-based support for efficacy or safety. In one study, which included eight patients with PE, a mixture of phentolamine mesylate 1 mg/mL and papaverine hydrochloride 30 mg/mL was injected. All patients reported satisfaction with the results of this treatment, but ejaculation delay was not objectively measured (Fein, 1990). Intracavernosal injection of vasoactive drugs is not recommended for the treatment of PE (level of evidence 4).

Acupuncture

One randomized placebo-controlled clinical study compared effectiveness of acupuncture therapy (twice per week) with paroxetine 20 mg/day and placebo (sham acupuncture) in the treatment of PE (Sunay et al, 2011). The authors included 90 patients with PE and demonstrated that acupuncture had a significantly stronger ejaculation-delaying effect than placebo (65.7 vs. 33.1 seconds), although it was less effective than daily paroxetine (82.7 seconds) ($P = .001$). Similarly, the patient-reported outcome measures showed an improvement in the acupuncture and paroxetine groups.

Surgical Neurotomy, Cryoablation, and Neuromodulation of the Dorsal Penile Nerve

Selective dorsal nerve neurotomy or hyaluronic acid gel glans penis augmentation is not recommended for the treatment of PE. Surgery may be associated with permanent loss of sexual function and is contraindicated in the management of PE. Several authors have reported the use of surgically induced penile hypoanesthesia via selective dorsal nerve neurotomy or hyaluronic acid gel glans penis augmentation in the treatment of lifelong PE refractory to behavioral and/or pharmacologic treatment (Kim et al, 2004; Perelman, 2006; Kwak et al, 2008; Shi et al, 2008; Basal et al, 2010). The role of surgery in the management of PE remains unclear until the results of further studies have been reported.

TABLE 29-2 Drug Therapy for Premature Ejaculation (PE)

DRUG	DOSE	DOSING INSTRUCTIONS	INDICATION	COMMENTS	LEVEL OF EVIDENCE
Dapoxetine	30-60 mg	On demand, 1-3 hr before intercourse	Lifelong PE Acquired PE	Approved in >50 countries	High
Paroxetine	10-40 mg	Once daily	Lifelong PE Acquired PE		High
Sertraline	50-200 mg	Once daily	Lifelong PE Acquired PE		High
Fluoxetine	20-40 mg	Once daily	Lifelong PE Acquired PE		High
Citalopram	20-40 mg	Once daily	Lifelong PE Acquired PE		High
Clomipramine	12.5-50 mg	Once daily	Lifelong PE Acquired PE		High
	12.5-50 mg	On demand, 3-4 hr before intercourse	Lifelong PE Acquired PE		High
Tramadol	25-50 mg	On demand, 3-4 hr before intercourse	Lifelong PE Acquired PE	Potential risk for opiate addiction	Low
Topical lignocaine/prilocaine	Patient titrated	On demand, 20-30 min before intercourse	Lifelong PE Acquired PE		High
Alprostadil	5-20 µg	Patient administered intracavernous injection 5 min before intercourse	Lifelong PE Acquired PE	Risk for priapism and corporal fibrosis	Very low
PDE5 inhibitors	Sildenafil 25-100 mg Tadalafil 10-20 mg Vardenafil 10-20 mg	On demand, 30-50 min before intercourse	Lifelong and acquired PE in men with normal erectile function	? Improved efficacy if combined with SSRI	Very low
			Lifelong and acquired PE in men with ED		Moderate

ED, erectile dysfunction; PDE5, phosphodiesterase type 5; SSRI, selective serotonin reuptake inhibitor.

causes of delayed ejaculation, anejaculation, and anorgasmia are manifold.

Definition, Terminology, and Characteristics of Men with Delayed Ejaculation

Delayed ejaculation (DE), retarded ejaculation (RE), or inhibited ejaculation (IE) are probably the least common, least studied, and least understood of the male sexual dysfunctions. Yet their impact is significant in that it typically results in a lack of sexual fulfillment for both the man and his partner, an effect further compounded when procreation is among the couple's goals of sexual intercourse.

Problems with "difficulty" in ejaculating may range from varying delays in the latency to ejaculation to complete inability to ejaculate (anejaculation). Reductions in the volume, force, and sensation of ejaculation may occur as well. At the extremes are anejaculation (time) and retrograde ejaculation (direction), but more commonly encountered are IE, RE, and DE. A final disorder, anorgasmia, refers to a perceived absence of the orgasm experience, independent of whether any or all of the physiologic concomitants of ejaculation have taken place.

Terminology and Definition

RE, DE, IE, inadequate ejaculation, idiopathic anejaculation, primary impotentia ejaculations, and psychogenic anejaculation all

have been used synonymously to describe a delay or absence of male orgasmic response. If a distinction is to be made, usually IE is characterized by the complete absence of ejaculation, although no clear consensus exists. Herein, the preferred terminology DE is meant to describe any and all of the ejaculatory disorders resulting in a delay or absence of ejaculation.

DSM-IV-TR defines DE as follows ([American Psychiatric Association, 2000](#)):

The persistent or recurrent delay in, or absence of, orgasm after a normal sexual excitement phase during sexual activity that the clinician, taking into account the person's age, judges to be adequate in focus, intensity, and duration. The disturbance causes marked distress or interpersonal difficulty; it should not be better accounted for by another Axis I (clinical) disorder or caused exclusively by the direct physiologic effects of a substance or a general medical condition.

Similarly, the Second International Consultation on Sexual Dysfunction defines DE as the persistent or recurrent difficulty, delay in, or absence of attaining orgasm after sufficient sexual stimulation, which causes personal distress ([McMahon et al, 2004a](#)).

No clear criteria exist as to when a man actually meets the conditions for DE, because operationalized criteria do not exist. Given that most sexually functional men ejaculate within approximately 4 to 10 minutes after intromission ([Patrick et al, 2005](#)), a clinician might assume that men with latencies beyond 25 or 30 minutes (21 to 23 minutes represents approximately 2 standard

deviations above the mean) who report distress or men who simply cease sexual activity because exhaustion or irritation qualify for this diagnosis. Such symptoms, together with the fact that a man and/or his partner decide to seek help for the problem, are usually sufficient for a DE diagnosis.

Epidemiology of Delayed Ejaculation

The prevalence of ejaculatory disorders is unclear, partly because of the dearth of normative data for defining the duration of “normal” ejaculatory latency, particularly regarding the right “tail” of the distribution (i.e., beyond the mean latency to orgasm). Furthermore, larger epidemiologic studies have not subdivided various types of ejaculatory disorders (e.g., delayed vs. absent), further limiting our knowledge. In general, DE is reported at low rates in the literature, rarely exceeding 3% (Laumann et al, 1999; Simons and Carey, 2001; Perelman, 2004). The prevalence of DE appears to be moderately and positively related to age, which is not surprising in view of the fact that ejaculatory function as a whole tends to diminish as men age.

Failure of ejaculation can be a lifelong problem or an acquired problem. It may be global and happen in every sexual encounter or be intermittent or situational. Normative descriptive data from large samples of men with DE have not been available, but a recent analysis identified 25% of a clinical sample with lifelong DE, with the remainder reporting a secondary problem (Perelman, 2004). Although coital anejaculation is frequently the treatment driver (especially for extremely religious individuals referred for fertility problems), men also seek treatment when distressed by their inability to achieve orgasm in response to manual, oral, or vaginal stimulation by their partner. Many men with acquired DE can masturbate to orgasm, whereas others, for multiple reasons, will not or cannot. Loss of masturbatory capacity secondary to emotional or physical trauma also is seen. Approximately 75% of one clinical sample could reach orgasm through masturbation, whereas the remainder either would not or could not (Perelman, 2004).

Similar to men with other types of sexual dysfunction, men with DE indicate high levels of relationship distress, sexual dissatisfaction, anxiety about their sexual performance, and general health issues—significantly higher than sexually functional men. In addition, along with other sexually dysfunctional counterparts, men with DE typically report lower frequencies of coital activity (Rowland et al, 2005). A distinguishing characteristic of men with DE—and one that has implications for treatment—is that they usually have little or no difficulty attaining or keeping erections; in fact they are often able to maintain erections for prolonged periods. But despite their good erections, they report low levels of subjective sexual arousal, at least compared with sexually functional men (Rowland et al, 2004b).

Cause of Delayed Ejaculation and Anejaculation

DE and anejaculation may be lifelong or acquired, global, or situational. A number of pathophysiologic conditions have been associated with ejaculatory problems (Box 29-2). These include congenital disorders as well as ones caused by psychological factors, treatment of male pelvic cancers with surgery or radiotherapy, neurologic disease, endocrinopathy, infection, and treatment for other disorders. When a medical history or symptomatology so indicates, investigation of such possible causes may be necessary. The most common causes of DE seen in clinical practice are psychogenic IE, degeneration of penile afferent nerves and pacinian corpuscles in the aging male, hypogonadism, diabetic autonomic neuropathy, treatment with SSRI antidepressants and major tranquilizers, radical prostatectomy or other major pelvic surgery, or radiotherapy.

Psychological Delayed Ejaculation

Psychogenic DE, often described as IE, is usually related to sexual performance anxiety, which may draw the man’s attention away

BOX 29-2 Causes of Retrograde Ejaculation, Delayed Ejaculation, Anejaculation, and Anorgasmia

AGING MALE

Degeneration of penile afferent nerves

PSYCHOGENIC

Inhibited ejaculation

CONGENITAL

Müllerian duct cyst
Wolffian duct abnormality
Prune belly syndrome

ANATOMIC CAUSES

Transurethral resection of prostate
Bladder neck incision

NEUROGENIC CAUSES

Diabetic autonomic neuropathy
Multiple sclerosis
Spinal cord injury
Radical prostatectomy
Proctocolectomy
Bilateral sympathectomy
Abdominal aortic aneurysmectomy
Para-aortic lymphadenectomy

INFECTIVE

Urethritis
Genitourinary tuberculosis
Schistosomiasis

Hypothyroidism

MEDICATION

α-Methyldopa
Thiazide diuretics
Tricyclic and SSRI antidepressants
Phenothiazine
Alcohol abuse
SSRI, selective serotonin reuptake inhibitor.

from erotic cues that normally serve to enhance arousal. Other psychodynamic explanations emphasize psychosexual development issues and have attributed lifelong DE to a wide range of conditions, including fear, anxiety, hostility, orthodoxy of religious belief, and relationship difficulties (Munjack and Kanno, 1979; Waldinger and Schweitzer, 2005). Although some of these factors may contribute to DE in individual men, no well-controlled studies provide broad support, at this point, for any of the various hypotheses mentioned previously (Waldinger and Schweitzer, 2005).

Masters and Johnson (1970) were the first to suggest that DE in some men might be associated with orthodoxy of religious belief. Such beliefs may limit the sexual experience necessary for learning to ejaculate or may result in an inhibition of normal function. Many devoutly religious men have masturbated only minimally or not at all, and, for some, guilt and anxiety about “spilling seed” may have led to idiosyncratic masturbatory patterns, which in turn resulted in DE. Such men often had little contact with women before marriage and, although they may have dated, were less likely than their

secular counterparts to experience orgasm with a partner, especially through intercourse.

Idiosyncratic and vigorous masturbation styles that cannot be replicated during intercourse with a partner, or an “autosexual” orientation in which men derive greater arousal and enjoyment from masturbation than from intercourse, are risk factors for DE (Perelman, 2005; Perelman and Rowland, 2006). These men precondition themselves to possible difficulty attaining orgasm with a partner and, as a result, experience acquired DE. They appear able to achieve erections sufficient for intercourse despite a relative absence of subjective arousal (Apfelbaum, 1989), and their erections are taken as erroneous evidence by both the man and his partner that he was ready for sex and capable of achieving orgasm. Disparity between the reality of sex with the partner and the sexual fantasy used during masturbation may inhibit sexual arousal and thus represent another contributor to DE (Perelman, 2001).

Endocrinopathy

Hypothyroidism is commonly strongly associated with DE, whereas hyperthyroidism is rarely associated with PE (Carani et al, 2005; Corona et al, 2006). Similarly, **hypogonadism** and low testosterone are associated with DE or anejaculation (Corona et al, 2008, 2011, 2012). **Hyperprolactinemia**, via inhibition of hypothalamic gonadotropin-releasing hormone GnRH is associated with low testosterone, reduced sexual desire, ED, and DE. The effect of prolactin on ejaculation is possibly mediated via its action on the serotonergic system (Corona et al, 2006, 2009).

Iatrogenic Causes

Any prescribed or recreational drug that changes the levels of neurotransmitters such as serotonin, dopamine, or oxytocin that are involved in the central or peripheral neurocontrol of ejaculation may affect ejaculatory latency.

SSRIs are commonly used for the treatment of depression and are associated with a high incidence of sexual dysfunction, with up to 60% reporting some form of treatment-related sexual dysfunction, most commonly ejaculatory dysfunction (Montejo et al, 2001; Delgado et al, 2005; Madeo et al, 2008). Treatment with **antipsychotics**, probably resulting from either a direct and/or indirect dopamine antagonism (Hull et al, 2004) or increased prolactin levels (Roke et al, 2012), is also commonly associated with DE and retrograde ejaculation (Madhusoodanan and Brenner, 1996; Raja, 1999). Retrograde ejaculation associated with antipsychotics is thought to be due to antagonistic effects on the α -adrenergic system at the level of the bladder neck (Holtmann et al, 2003).

Treatment of Male Pelvic Cancers

Overall quality of life and sexual functioning have evolved as key issues in the management of patients with cancer. Because of modern surgical techniques, improved quality of drugs for chemotherapy, and modern radiation techniques, more patients can be successfully treated without largely compromising sexual functioning.

Prostate Cancer

Prostate cancer has become the most common nonskin malignancy in men in Western countries. External-beam radiotherapy (EBRT) and brachytherapy (BT) are, together with the open or robotic radical prostatectomy (RP/RALP), the most common and effective treatments for localized prostate cancer. Despite the introduction of very modern radiotherapy (RT) techniques, sexual functioning after prostate cancer treatment remains problematic for many patients. **After RP/RALP, men no longer ejaculate, but maintain a sense of orgasm** that can vary from less to more intense than preoperatively and may experience arousal urinary incontinence or climacturia—that is, urinary incontinence at orgasm.

Ejaculatory disturbances after RT of prostate cancer were reported as early as the 1980s (Van Heeringen et al, 1988). More recent

studies have evaluated the impact of RT on sexual desire, ejaculation, and orgasm. **After EBRT, a decline in sexual desire was reported by 43% of 64 patients and a decreased frequency of orgasm by 57%; all men reported a decrease in ejaculate volume (Helgason et al, 1995).** Using a validated questionnaire, Borghede and Hedelin (1997) reported a decrease in the ability to ejaculate in 56% of the patients. Good prognostic factors for sexual functioning preservation after RT were low age and higher frequency of intercourse.

Early RT studies also assessed sexual functioning. Herr (1979) reported already in 1979 on 51 patients treated with retropubic iodine-125 seeds, with loss of ejaculate experienced by 6% of the patients. In a later study, dry ejaculation was reported by 16% of the patients after BT (Kwong et al, 1984). In both studies, all patients had previously undergone a transurethral resection of the prostate (TURP). For the first time a discomfort with ejaculation was mentioned in two studies (up to 25% of the patients) (Kleinberg et al, 1994; Arterbery et al, 1997). This result is quite common in clinical practice after BT, because of edema of the prostate possibly reducing the elasticity of the urethra and inducing discomfort with ejaculation. In some patients, discomfort with ejaculation did not disappear even 18 to 24 months after BT (Beckendorf et al, 1996). Also, decreased interest in sex, sexual desire, and libido was mentioned in up to 50% of the patients evaluated (Beckendorf et al, 1996; Arterbery et al, 1997; Borghede and Hedelin, 1997; Joly et al, 1998).

Several studies on the cause of post-RT decreased libido and ejaculatory disorders have been reported. Daniell and associates (2001) studied retrospectively levels of testosterone and other hormones after RT of prostate cancer. Testosterone was found to be low 3 to 8 years after EBRT, with lower levels found in older patients. Although testes are very sensitive to radiation, spermatogenesis is more easily affected than androgen productions. The radiation dose calculated in the testes of men irradiated for prostate cancer is only 3% to 8% of the dose that could possibly affect androgen production and could explain a decrease in testosterone. A TURP carries a high incidence of retrograde ejaculation because it is thought to disrupt the closure mechanism of the vesical neck; this could explain ejaculatory disturbances in most patients after previous TURP.

Rectal Carcinoma

Not much is known about sexual functioning after RT of rectal carcinoma. Preoperative RT for rectal cancer has been associated with a reduction in the rate of local relapse and possibly an advantage in survival. Preoperative RT with the total mesorectal excision in low-stage rectal cancer has become a common procedure in Europe. **A sharp dissection of the mesorectum associated with visualization and preservation of the pelvic autonomic nerve leads to excellent results regarding erectile and ejaculatory functioning.** Only one study has specifically studied the effects of preoperative RT for rectal carcinoma on male sexual functioning and concluded that it may impair male sexual functioning (Bonnell et al, 2002). However, numbers were too small to draw final conclusions.

Testicular Cancer

Germ cell tumors of the testis are relatively rare, accounting for approximately 1% of all male cancers. The long-term survival for early disease approaches 100%. Because testicular cancer affects mainly young men in their sexual and fertile life, sexual functioning and ejaculatory disorders are particularly important. The side effects of retroperitoneal lymph node dissection (RPLND) for residual mass after chemotherapy for nonseminomatous cancer are better documented than sexual sequelae of elective abdominal RT for seminoma. **Anejaculation occurs in the majority of the patients in non-nerve-sparing techniques.** As a result of careful anatomic studies, the technique of RPLND has been modified with nerve sparing so that antegrade ejaculation is now maintained in 80%

TABLE 29-3 Correlation of Erection, Ejaculation, and Intercourse with Level and Severity of Spinal Cord Injury

CORD LESION		REFLEXOGENIC ERECTIONS (%)	PSYCHOGENIC ERECTIONS (%)	SUCCESSFUL COITUS (%)	EJACULATION (%)
Upper motor neuron	Complete	92	9	66	1
	Incomplete	93	48	86	22
Lower motor neuron	Complete	0	24	33	15
	Incomplete	0	1	100	100

From Comarr AE. Sexual function among patients with spinal cord injury. *Urol Int* 1970;25:134–68.

to 100% of patients (van Basten et al, 1997). Libido and orgasm seem to be normal in these patients.

After RT, deterioration in sexual functioning has been reported in 1% to 25% of the patients (Schover et al, 1986; Tinkler et al, 1992; Jonker-Pool et al, 1997; Caffo and Amichetti, 1999; Incrocci et al, 2002). Tinkler and colleagues (1992) reported on 237 patients after orchiectomy and abdominal RT and compared these data to 402 age-matched controls. In almost all parameters studied, including erection, ejaculation, and libido, patients scored less than controls (reduction in orgasm, in libido, and interest in sex). Specifically, there was no difference in the ability to ejaculate during sexual activity, but the patients undergoing RT reported a noticeable reduction in the amount of semen compared to before treatment. Caffo and Amichetti (1999) evaluated toxicity and quality of life in 143 patients treated for early-stage testicular cancer. Of these, 23% reported a decreased libido, 27% problems with getting an orgasm, and 38% ejaculation disturbances, including PE. A decrease in sexual desire, orgasm, and volume or semen was negatively correlated with age (Schover et al, 1986). Jonker-Pool and associates (1997) reported on three groups of patients, after RT, wait and see, and chemotherapy. Patients undergoing RT reported decreased libido in 22% compared to 12% in the wait-and-see group and 30% in the chemotherapy group. Decrease or absence of ejaculate was reported in 15%, 7%, and 21% in the three groups, respectively; decreased orgasm was found in 15%, 12%, and 30%, respectively. Although the differences were not statistically significant, in the RT group, ejaculation and orgasm disturbances were higher than in the wait-and-see group. Similar results were reported by Arai and coworkers (1997). PE was reported in up to half of the patients (Arai et al, 1997; Incrocci et al, 2002), but it was the same as recalled before treatment (Incrocci et al, 2002).

The superior hypogastric plexus is responsible for ejaculation and is mediated by the sympathetic system; it is a fenestrated network of fibers anterior of the lower abdominal aorta. The hypogastric nerves exit bilaterally at the inferior pole of the superior hypogastric plexus and have connections with the S1 to S2 roots. Normal emission requires integrity of this system. During RPLND, these nerves are difficult to recognize and might be damaged, resulting in decreased semen volume or dry ejaculation. Pathways for ejaculation are included in the RT fields for rectal and prostate carcinomas. Damage of the sympathetic nerves could be caused by radiation, but the dose does not seem enough to completely explain the dysfunction. Orgasm is even more complex than ejaculation, because it is also affected by cortical input.

Neurologic Disorders

Degeneration of penile fast-conducting afferent nerves and pacinian corpuscles in the aging male, diabetic autonomic neuropathy, multiple sclerosis, and spinal cord injury are often associated with DE/anejaculation.

Spinal Cord Injury

The ability to ejaculate is severely impaired by spinal cord injury (SCI). Bors and Comarr highlighted the impact of the level and completeness of SCI on the postinjury erectile and ejaculatory

capacity (Bors and Comarr, 1960; Comarr, 1970) (Table 29-3). Unlike erectile capacity, the ability to ejaculate increases with descending levels of spinal injury. Fewer than 5% of patients with complete upper motor neuron lesions retain the ability to ejaculate. Ejaculation rates are higher (15%) in patients with both lower motor neuron lesions and an intact thoracolumbar sympathetic outflow. Approximately 22% of patients with an incomplete upper motor neuron lesion and almost all men with incomplete lower motor neuron lesions retain the ability to ejaculate. In patients capable of successful ejaculation, the sensation of orgasm may be absent and retrograde ejaculation often occurs.

Several techniques for obtaining semen in men with SCI with ejaculatory dysfunction have been reported. Vibratory stimulation is successful in obtaining semen in up to 70% of men with SCI (Brindley, 1984). The use of electroejaculation to obtain semen by electrical stimulation of efferent sympathetic fibers of the hypogastric plexus is an effective and safe method of obtaining semen. Brindley (1986) reported that 71% of men with SCI who underwent electroejaculation achieved ejaculation. However, both vibratory stimulation and electroejaculation are associated with a significantly high risk for autonomic dysreflexia. Pretreatment with a fast-acting vasodilator such as nifedipine minimizes the risk for severe hypertension, should autonomic dysreflexia occur with either form of treatment (Steinberger et al, 1990).

Semen collected from men with SCI is often initially senescent and of poor quality with a low sperm count and reduced sperm motility but may improve with subsequent ejaculations. This poor semen quality may be due to chronic urinary tract infection, dilution of sperm content with urine, chronic use of various medications, elevated scrotal temperature as a result of prolonged sitting, and stasis of prostatic fluid. Testicular biopsies in men with SCI demonstrate a wide range of testicular dysfunction including hypospermatogenesis, maturation arrest, atrophy of seminiferous tubules, germinal cell hypoplasia, interstitial fibrosis, and Leydig cell hyperplasia. In addition, prostatitis secondary to prolonged catheterization, epididymitis, and epididymo-orchitis can precipitate obstructive ductal lesions and testicular damage. Ohl and associates (1989) reported that sperm density and motility were higher in those with incomplete lesions. In a recent collective analysis of 40 paraplegic patients, 22 successfully produced pregnancies by natural insemination or assisted reproductive techniques (Dahlberg et al, 1995).

Congenital Disorders

Typical congenital problems include müllerian duct obstruction, caused by failure of complete absorption of müllerian duct remnants in males; wolffian duct abnormalities, which may compromise vas deferens, ejaculatory duct, and seminal vesicle functioning; and prune belly syndrome.

Infective Disorders

Sexually transmissible infections such as gonorrhea or nonspecific urethritis can produce cicatrization and obstruction anywhere in the male reproductive tract, especially if treatment is delayed. Urinary infection, especially if complicated by epididymitis, also

can produce obstruction that may be situated at the ejaculatory duct level. Schistosomiasis is endemic in large parts of Africa and is seen with increasing frequency in tourists returning from Africa who have contracted the disease while enjoying water sports. The disease may manifest with hemospermia (McKenna et al, 1997), and fibrosis and calcification may lead to genital obstruction. Genitourinary tuberculosis can cause great damage to the male reproductive tract, and because healing occurs with calcification, the lesions may be irreparable.

Evaluation of Men with Delayed Ejaculation

Evaluation of men presenting with DE or anejaculation should include a **full medical and sexual history, a focused physical examination, determination of serum testosterone levels, and any additional investigations suggested by these findings.**

Assessment begins by determining whether DE is lifelong or acquired, global or situational (Box 29-3). Evaluation includes establishment of how often a man can ejaculate during intercourse and the time elapsed between penetration and ejaculation, the IELT. If ejaculation fails to occur, the duration of thrusting before suspension of intercourse, the reasons for suspension of intercourse (e.g., fatigue, loss of erection, a sense of ejaculatory futility, or partner request), and whether ejaculation can occur during postcoital

BOX 29-3 Recommended and Optional Questions to Establish the Diagnosis of Delayed Ejaculation (DE) and Direct Treatment

RECOMMENDED QUESTIONS FOR DIAGNOSIS OF DE For Diagnosis

How often can you ejaculate during sexual intercourse?
During intercourse, how long after penetration does it take for you to either ejaculate or stop intercourse?
When you cannot ejaculate during sexual intercourse, how often do you feel that you are close to ejaculation?
If you cannot ejaculate, why do you stop intercourse?
Do you ever feel that you have ejaculated but fail to release semen?
Do you feel bothered, annoyed, and/or frustrated by your DE?
How often can you ejaculate during masturbation by yourself or with your partner?

OPTIONAL QUESTIONS

Differentiate Lifelong and Acquired DE

When did you first experience DE?
Have you experienced DE since your first sexual experience on every/almost every attempt and with every partner?

Assess Erectile Function

Is your erection hard enough to penetrate?
Do you have difficulty in maintaining your erection during intercourse?

Assess Relationship Impact

How upset is your partner with your DE?
Do you or your partner avoid sexual intercourse?
Is your DE affecting your overall relationship?

Previous Treatment

Have you received any treatment for your DE previously?

Impact on Quality of Life

Do you feel anxious, depressed, or embarrassed because of your DE?

self- or partner-assisted masturbation must be determined. The presence or absence of premonitory ejaculatory sensation during intercourse or masturbation suggests achievement of sufficient arousal to almost attain the ejaculation threshold. Variables that improve or worsen performance are noted. The man's ability to relax, sustain, and heighten arousal and the degree to which he can concentrate on sensations are noted.

The presence and extent of patient, partner, or interpersonal related negative psychological consequences such as bother, distress, frustration, or the avoidance of sexual contact should be established. The frequency of intercourse and the identity of the initiator of sexual contacts are useful surrogate measures for these negative psychological consequences. The quality of the nonsexual relationship also should be explored.

In men with acquired DE, previous illness, surgery, medications, or life events or circumstances should be reviewed. The events may include a variety of life stressors and other psychological factors (e.g., after his wife's mastectomy the man is afraid of hurting her and therefore is only partially aroused). Societal and religious attitudes that may interfere with excitement are noted, such as the "spilling of seed as a sin."

A **focused physical and genital examination** to determine whether the testes and epididymes are normal and whether the vasa are present or absent on each side, supported by a screening morning total testosterone level and any other hormonal or imaging investigations indicated by either history or physical examination, will identify or exclude organic disease. Digital rectal examination to determine prostate size, anal sphincter tone, and quality of the bulbocavernosus reflex is indicated in most men, with the exception of young men with situational and clear psychogenic IE. The presence of a neuropathy may require electrophysiologic evaluation of neural pathways controlling ejaculation, pudendal somatosensory and motor evoked potentials, sacral reflex arc testing, and sympathetic skin responses.

The occurrence of orgasm in the absence of prograde ejaculation suggests retrograde ejaculation and can be confirmed by the presence of spermatozoa in postmasturbation first-void urine. If the cause of DE is unclear, culture of expressed prostatic secretion and urine, urine cytology, and serum prostate-specific antigen will exclude prostatitis and bladder and prostatic cancer. Ultrasound scan of the testicles and epididymes may define any local disease.

Patients with unilateral or bilateral ejaculatory duct obstruction or congenital absence of vasa usually present with thin/runny low-volume semen, aspermia, and infertility. Seminal analysis demonstrates azoospermia or oligospermia with low concentration of fructose and a low pH. Ultrasound scanning of the entire urinary system and referral to a urologist is indicated because coexisting renal anomalies may be present. Bilateral absence or malformation of the vasa may be associated with the cystic fibrosis gene (Mickle et al, 1995).

Treatment of Men with Delayed Ejaculation or Anejaculation

Figure 29-4 is a flow chart for the management of DE (Rowland et al, 2010). Treatment should be cause specific, address the issue of infertility in men of reproductive age, and may include **patient/couple psychoeducation and/or psychosexual therapy, pharmacotherapy, or integrated treatment.** Men/partners of reproductive age undergoing pelvic surgery should be informed of the risk for infertility as a result of anejaculation and the availability of sperm harvesting and assisted reproductive techniques.

Whether a clear pathophysiologic cause is present or absent, patients might be counseled to consider **lifestyle changes, including enjoying more time together to achieve greater intimacy, minimizing alcohol consumption, making love when not tired, and practicing techniques that maximize penile stimulation such as pelvic floor training (Waldinger and Schweitzer, 2005).** Neuro-pathic DE is usually irreversible, and therefore the patient might be counseled to seek alternative methods to achieve mutual sexual satisfaction with his partner.

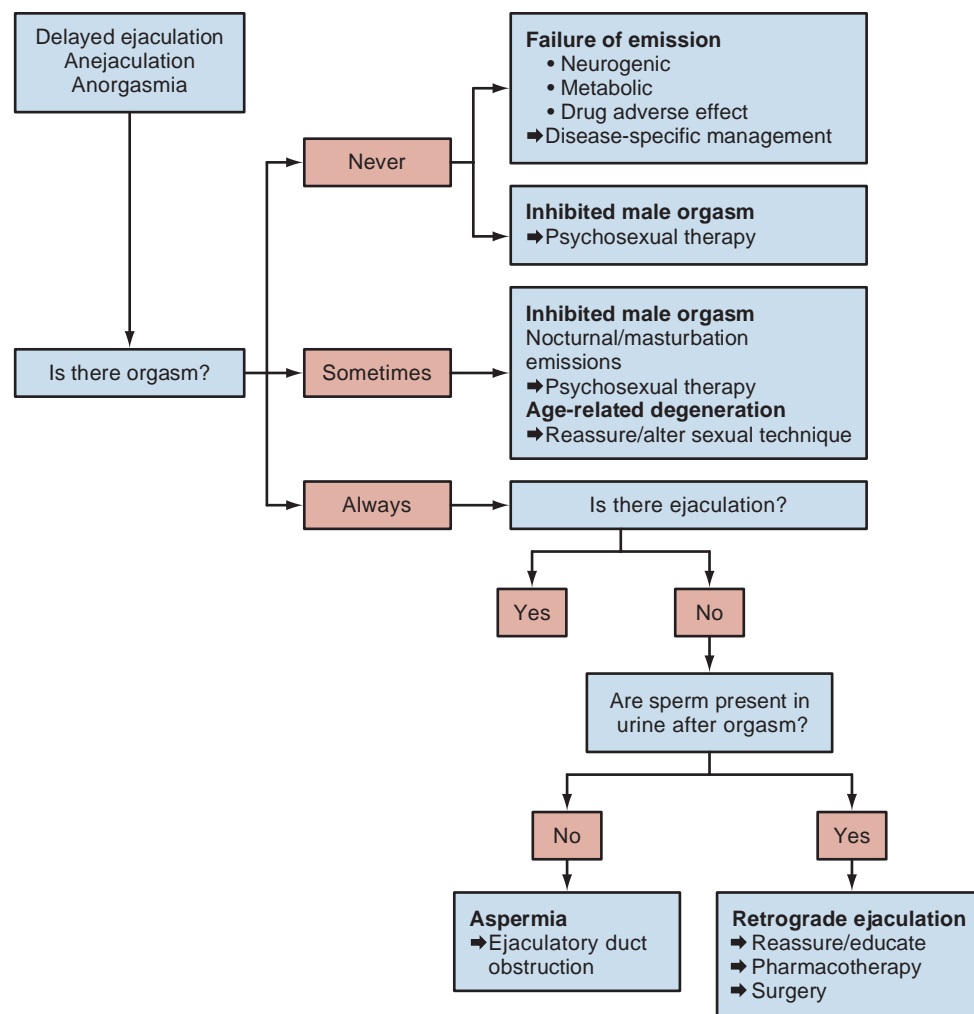

Figure 29-4. Algorithm for the office management of delayed ejaculation, anejaculation, and anorgasmia.

Psychological Strategies in the Treatment of Delayed Ejaculation

If organic and pharmacologic causes have been eliminated, referral to an expert psychosexual therapist is usually indicated to evaluate the causative psychological and behavioral issues. Beneficial effects through psychotherapy depend on the severity of the DE and the individual's receptiveness to engage in counseling and adhere to the counselor's recommendations.

Additional information on the role of psychosexual therapy in the management of DE is available on the Expert Consult website.

Pharmacotherapy in the Treatment of Delayed Ejaculation

Drug treatment of DE or IE ejaculation has met with limited success (Table 29-4). These drugs facilitate ejaculation by either a central dopaminergic, antiserotonergic, or oxytocinergic mechanism of action or a peripheral adrenergic mechanism of action. However, no drugs have been approved by regulatory agencies for this purpose and most drugs that have been identified for potential use have limited efficacy, impart significant side effects, or are as yet considered experimental in nature. Results are relatively poor in men with psychogenic DE and neuropathic DE.

α_1 -Adrenergic receptor agonists such as on-demand precoital pseudoephedrine (60 to 120 mg 1 to 2 hours before intercourse) or the selective norepinephrine reuptake inhibitor (SNRI) antidepressant reboxetine (4 to 8 mg daily) which inhibits synaptic noradrenaline reuptake have limited efficacy. The antihistamine cyproheptadine, a central serotonin antagonist, is anecdotally

TABLE 29-4 Drug Therapy for Delayed Ejaculation and Anejaculation

DRUG	DOSAGE	
	AS NEEDED	DAILY
Cabergoline	—	0.5-2 mg every 3 days
Amantadine	100-400 mg (for 2 days before coitus)	100-200 mg twice daily
Pseudoephedrine	60-120 mg (1-2 hr before coitus)	—
Reboxetine	—	4-8 mg
Oxytocin	24 IU intranasal during coitus	—
Bupropion	—	150 mg/day or twice daily
Buspirone	—	5-15 mg twice daily
Cyproheptadine	4-12 mg (3-4 hr before coitus)	—

The partner and the quality of the relationship warrant exploration. Numerous psychotherapeutic processes are described for the management of DE or IE (McCarthy, 1981; Apfelbaum, 1989) and some appear to be effective, but none has been properly evaluated in large-scale samples (McMahon et al, 2006b). Among these strategies are: (1) sex education; (2) reduction of goal-focused anxiety; (3) increased, more genitally focused stimulation; (4) patient role-playing an exaggerated ejaculatory response on his own and in front of his partner; (5) masturbatory retraining; and (6) realignment of sexual fantasies and arousal strategies.

Most current sex therapy approaches to DE emphasize the importance of masturbation in the treatment of DE, with most of the focus on “masturbatory retraining” integrated into sex therapy (Kaplan, 1995). Typically, self-stimulation techniques incorporating fantasy can be used to achieve incremental increases in arousal that eventually enable orgasm. Fantasy can serve the purpose of increasing arousal and blocking inhibiting thoughts that might otherwise interfere. Once the man’s ejaculatory ability is established through masturbation, the same skill set can be incorporated into sex with the partner.

An important component in the treatment of any type of DE is the removal of the “demand” (and thus anxiety-producing) characteristics of the situation (Apfelbaum, 1989). “Ejaculatory performance” anxiety can interfere with the erotic sensations of

genital stimulation and may result in levels of sexual excitement insufficient for climax (although they may be more than adequate to maintain an erection). To reduce anxiety, treatment may include recognition of the overeagerness of men with DE to please their partners, validation of (though not necessarily encouragement of) the man’s autosexual orientation, removal of stigmas suggesting hostility or withholding toward their partner, and general anxiety reduction techniques such as relaxation and desensitization.

The partner also needs to collaborate in the therapeutic process, finding ways to enhance the man’s arousal and accepting the use of erotica and various (harmless) sexual fantasies that also might be incorporated into the couple’s lovemaking. Furthermore, because interventions used in the treatment of DE may be experienced by the female partner as mechanistic (e.g., using a stepwise program) and insensitive to her sexual needs, the therapeutic challenge is to facilitate the rapport between the partners, while maintaining a therapeutic alliance with both partners and simultaneously optimizing his response to her manual, oral, and vaginal stimulation.

The success of treating DE is difficult to assess from the literature (McMahon et al, 2006b) because the evidence on the effectiveness of various treatments is limited (Heiman and Meston, 1997) and both successful and unsuccessful case reports have been cited (Apfelbaum, 1989).

associated with the reversal of anorgasmia induced by the SSRI antidepressants, but no controlled studies have been reported (McCormick et al, 1990; Ashton et al, 1997). These studies suggest an effective dose range of 4 to 12 mg 3 to 4 hours before intercourse, with administration on a chronic or on-demand basis. However, significant dose-related sedative effects are likely to diminish its overall efficacy.

Amantadine, an indirect stimulant of dopaminergic nerves both centrally and peripherally, has been reported to stimulate sexual behavior and ejaculation in SSRI antidepressant-induced anorgasmia when administered on demand (100 to 400 mg 2 days before coitus) or chronically (100 to 200 mg twice daily) (Balogh et al, 1992).

A variety of other pharmacologic agents, including **cabergoline**, **bromocriptine**, **bupropion**, and **buspirone** have been anecdotally reported as potential DE pharmacotherapy, despite an absence of large-population RCTs. Of interest is the recent single case report of the **intracoital administration of intranasal oxytocin** in a case of treatment-resistant anorgasmia (Ishak et al, 2008). However, in the absence of robust RCT data, oxytocin cannot be recommended as a treatment for DE.

KEY POINTS: DELAYED EJACULATION

- The causes of DE and anejaculation are manifold.
- Failure of ejaculation can be a lifelong problem (25%) or an acquired problem (75%). It may be global and occur in every sexual encounter or be intermittent or situational.
- Treatment of men with DE should be cause specific and address the issue of infertility in men of reproductive age.
- Drug treatment of men with DE or anejaculation has had limited success.

RETROGRADE EJACULATION

Antegrade (normal) ejaculation requires a closed bladder neck (and proximal urethra). **Surgical procedures that compromise the bladder neck closure mechanism may result in retrograde ejaculation.** Transurethral incision of the prostate (TUIP) results in retrograde ejaculation in 5% (Hedlund and Ek, 1985) to 45% (Kelly et al, 1989) of patients and is probably related to whether one or two incisions are made and whether the incision includes primarily the bladder neck or extends to the level of the verumontanum. The importance of contraction of the urethral smooth muscle at the level of the verumontanum has been hypothesized to be important in preventing retrograde ejaculation (Reiser, 1961). TURP carries a higher incidence of retrograde ejaculation than does TUIP. The reported incidence of retrograde ejaculation after TURP ranges from 42% (Edwards and Powell, 1982) to 100% (Quinlan et al, 1991). Although these men may have some antegrade ejaculation and usually experience orgasmic sensation, both events may be reduced as part of the changes that occur in the male sexual response as a man ages. Retrograde ejaculation is more common in diabetes mellitus than in age-matched controls ($P < .01$), has been reported in 30% of men with diabetes mellitus, and is not statistically associated with duration of diabetes mellitus, BMI, waist circumference, or hemoglobin A1c or total testosterone levels (Waldinger et al, 2005a).

Retrograde ejaculation and failure of emission can be distinguished by examination of a postmasturbatory specimen of urine for the presence of spermatozoa and fructose. The finding of more than 5 to 10 sperm per high-power field in a postejaculation urine specimen confirms the presence of retrograde ejaculation. In patients with low-volume ejaculate, the finding of more sperm in the urine than in the antegrade ejaculate indicates a significant component of retrograde ejaculation (Sigman and Howards, 1998).

Treatment of Retrograde Ejaculation

Retrograde ejaculation can be surgically treated with bladder neck reconstruction but results remain consistently poor (Abrahams et al, 1975; Lipshultz et al, 1981). Drug treatment is the most promising approach. As mentioned earlier, α -adrenergic sympathetic nerves mediate both bladder neck closure and emission. Several sympathomimetic amine agents have been described as useful with mixed results (Kedia and Markland, 1975). These drugs include **pseudoephedrine**, **ephedrine**, **midocrine**, and **phenylpropanolamine**. These agents work by stimulating the release of noradrenaline from the nerve axon terminals but also may directly stimulate both α - and β -adrenergic receptors. The most useful is pseudoephedrine, which is administered at a dose of 120 mg 2 to 2.5 hours precoital. The TCA **imipramine**, which blocks the reuptake of noradrenaline by the axon from the synaptic cleft is also occasionally useful. The usual dose is 25 mg twice daily. The current feeling is that long-term treatment with imipramine is likely to be more effective. Although medical treatment may not always produce normal ejaculation, it may result in some prograde ejaculation. In patients who do not achieve antegrade ejaculation with either surgery or medication, sperm retrieval and artificial insemination is an alternative approach. The basic method of sperm retrieval involves recovery of urine by either catheter or voiding after masturbation and then centrifugation and isolation of the sperm.

KEY POINTS: RETROGRADE EJACULATION

- TURP and diabetic autonomic neuropathy are the most common causes of retrograde ejaculation.
- Retrograde ejaculation and failure of emission can be distinguished by examination of a postmasturbatory specimen of urine for the presence of spermatozoa and fructose.
- Pharmacotherapy is associated with variable degrees of success and includes agents such as pseudoephedrine, midodrine, and imipramine.

PAINFUL EJACULATION

Painful ejaculation, or **odynorgasmia**, is a poorly characterized syndrome. It may be associated with **urethritis**, **BPH**, **acute or chronic prostatitis**, **CPPS**, **seminal vesiculitis**, **seminal vesicular calculi**, or **ejaculatory duct obstruction** (Weintraub et al, 1993; Corriere, 1997; Kochakam et al, 2001; Nickel et al, 2005). Often, no obvious etiologic factor can be found. **Painful ejaculation occurs in 17% to 23% of men with LUTS/BPH** (Frankel et al, 1998; Tubaro et al, 2001; Brookes et al, 2002; Vallancien et al, 2003). Men with BPH and painful ejaculation have more severe LUTS and report greater bother. In addition, they report a higher incidence of ED and a reduced ejaculation volume, compared to men with LUTS only (Rosen et al, 2003). Treatment of men with LUTS with α -blocking drugs may be associated with painful ejaculation. A lower incidence of pain has been reported with the uroselective α_1 -blocking drug, alfuzosin (van Moorselaar et al, 2005). Management should focus on treatment of the underlying cause.

POSTORGASMIC ILLNESS SYNDROME

POIS is a recently described but poorly characterized “orphan” disease comprising a **collection of symptoms that include severe myalgia and fatigue associated with a flulike state that occurs within 30 minutes of orgasm.**

Additional information on POIS is available on the Expert Consult website. 

People engage in sexual activity for a number of reasons. The feelings of calmness, contentment, and sedation after orgasm have been described as inducements for intercourse, particularly in men (Meston and Buss, 2007).

In 2002, Waldinger and Schweitzer described a collection of symptoms following orgasm in two males that were qualitatively similar but more extreme and prolonged than the expected state of relaxation and somnolence that would normally occur. The symptoms consisted of severe myalgia and fatigue associated with a flulike state after orgasm. The symptoms were severe enough that the individuals avoided ejaculating to try to prevent the symptoms. Waldinger and Schweitzer (2002) named this cluster of symptoms after ejaculation postorgasmic illness syndrome (POIS). To date, POIS is a rarely described syndrome, and despite having a significant impact on quality of life for individual sufferers, little is known about its epidemiology and cause.

Although POIS may appear to be an orphan disease, it may be more common than reported in the literature. In the *New York Times* in January 2009, Richard Friedman, a New York City psychiatrist, describes several patients who experience low mood and somatic symptoms after orgasm, whose symptoms improved with the use of SSRIs. Evidence of many more undiagnosed individuals with POIS is seen in the existence of an extremely active Internet forum in which more than 100 people have self-reported symptoms of POIS.

More recently, Waldinger and colleagues (2011b) reported 45 males with suspected POIS in whom symptoms did not occur during sexual contact without ejaculation. POIS symptoms started within 30 minutes after ejaculation in 87% of men. All men reported a gradual intensity peak of symptoms, most of which were experienced on day 2. Reports of POIS were categorized in seven clusters of symptoms: (1) a sensation of a flulike state; (2) extreme fatigue or exhaustion; (3) weakness of musculature; (4) experiences of feverishness or perspiration; (5) mood disturbances and/or irritability; (6) memory difficulties, concentration problems, incoherent speech; and (7) congestion of nose or watery nose, itching eyes. All symptoms occur immediately (e.g., seconds), soon (e.g., minutes), or within a few hours after ejaculation that is initiated by coitus, and/or by masturbation, and/or spontaneously (e.g., during sleep). Symptoms occur always or nearly always—that is, in more than 90% of ejaculation events. Most of these symptoms last for approximately 2 to 7 days and disappear spontaneously.

Waldinger and associates (2011b) proposed a type 1 hypersensitivity immunogenic mechanism as local allergic reactions of eyes and nose were reported in 44% and 33% of subjects, 58% had an atopic constitution, and 88% had a positive skin-prick test with their own semen. He suggested that autologous seminal peptides or peptides released from the disrupted urethral lining cells contact the inner mucosal epithelium of the urethra, are recognized and taken up by dendritic cells in the epithelium, and migrate to the T-cell zones of lymph nodes, where contact between the seminal fluid antigen(s) and naive T cells initiate the cascade of events of a hypersensitivity reaction. This may parallel the reports of an alloallergic reaction to specific protein fractions of seminal plasma in female partners of males if symptoms are localized but may include generalized urticaria and, rarely, anaphylactic shock (Ohman et al, 1990; Lee et al, 2008).

Of particular interest was the observation that 56% of this POIS study population also had lifelong PE with an IELT of 1 minute or less. In men with POIS, the relative risk for PE is 22.4-fold higher than in healthy individuals. This may be related to forced abstinence of, and therefore low frequency of, sexual activity.

In a third study, two men with POIS with positive autologous semen skin testing underwent a prolonged hyposensitization program with multiple subcutaneous injections of autologous semen and reported a gradual reduction of complaints and 60% and 90% amelioration of POIS complaints at 31 and 15 months, respectively (Waldinger et al, 2011a).

KEY POINTS: POST ORGASMIC ILLNESS SYNDROME

- The symptoms of POIS occur after ejaculation and are severe myalgia, fatigue associated with a flulike state, nasal congestion, and itching eyes.
- POIS symptoms commence within 30 minutes of ejaculation in 87% of men and increase in intensity to a peak on day 2.
- A type 1 hypersensitivity immunogenic reaction has been proposed as the underlying mechanism.
- A prolonged hyposensitization program with multiple subcutaneous injections of autologous semen has been suggested as a possible treatment.

CONCLUSION

Recent epidemiologic and observational research has provided new insights into PE and the associated negative psychosocial effects of this dysfunction. The recently developed multivariate evidence-based ISSM definition of lifelong and acquired PE provides the clinician a more discriminating diagnostic tool and should form the basis of the office diagnosis of lifelong PE.

Although insufficient empirical evidence exists to unequivocally identify the cause of PE, limited evidence suggests that lifelong PE may have a genetic basis and that acquired PE is most often due to sexual performance anxiety, psychological or relationship problems, and/or ED and to a lesser extent, chronic prostatitis, CPPS or hyperthyroidism.

Current evidence suggests that psychosexual cognitive behavioral therapy has a limited role in the contemporary management of PE and confirms the efficacy and safety of oral SSRI drugs and topical anesthetic drugs. It is likely that dapoxetine, despite its modest effect on ejaculatory latency, has a place in the management of PE, which will eventually be determined by market forces once the challenge of regulatory approval has been met. Treatment with tramadol, intracavernous injection therapy, or alternative methods of drug delivery cannot be recommended until the results of large, well-designed RCTs are published in major international peer-reviewed medical journals.

DE and anejaculation are more common as men age and have manifold organic and psychogenic causes. They have a significant impact on sexual fulfilment for both the man and his partner and may result in infertility. Treatment of men with DE represents one of the most significant challenges in sexual medicine and outcome results are often disappointing.

Conclusion

Penile prostheses have been used to treat erectile dysfunction (ED) since the mid 1970s (Scott et al, 1973; Small et al, 1975). In the United States, approximately 20,000 penile prosthetic devices are implanted annually, accounting for 75% of the global market (Mulcahy and Wilson, 2006; Garber, 2008). The primary goal of penile implant surgery is to restore erections that most closely resemble normal function in terms of rigidity, girth expansion, and length expansion. Because ED is often associated with feelings of inadequacy, disappointment, and loss of self-confidence, an additional goal of implant surgery is to improve a patient's quality of life and self-esteem. **Men who experience ED constantly think about their dysfunction. After prosthetic surgery for ED, they experience a sense of freedom that is very similar to being cured. This feeling is not reported by men who use other temporary treatment options for ED (Rajpurkar and Dhabuwala, 2003).**

Indications for a penile prosthetic device include failure or rejection of more conservative therapy for ED, Peyronie disease in which ED and erectile deformity coexist, irreversible organic etiology of ED, penile fibrosis, post priapism and unresponsive to more conservative treatment, phalloplasty following radical penile cancer surgery or gender change, and psychological impotence after failure of all other treatment (Anderson et al, 2007; Al-Enezi et al, 2011). Prosthetic implants are considered the most effective method for obtaining an artificial erection in patients with ED who are unresponsive to or cannot tolerate other treatment (Bettocchi et al, 2010).

TYPES OF PROSTHESES

There are two broad categories of penile implants, semirigid rods and inflatable devices, both of which were introduced almost 40 years ago and have undergone significant design improvements since that time (Scott et al, 1973; Small et al, 1975). The devices in both categories can be used to achieve penile rigidity, but there are differences in cosmetic appearance, and semirigid rods do not permit flaccidity. **The selection of a device may depend on a physician's surgical experience, insurance coverage, and patient preference and anatomy and/or history.**

Semirigid Rods

Semirigid rods are paired, solid cylinders that fill each corpus cavernosum. They can be further subdivided into malleable and positional devices (Figs. 30-1 and 30-2). A malleable device has a central core that allows a patient to position the penis upward for sexual intercourse and downward at other times. A positional device incorporates a series of articulating polyethylene discs with a central

metal cable support, which make it better able to maintain upward and downward positions. Semirigid rods are typically available in several diameters and lengths. Advantages of these prostheses are that they are relatively inexpensive, easy to implant (although a larger incision of the tunica albuginea is required), and easy to use. They also have a relatively low mechanical failure rate. Drawbacks are that they simulate a constant erection, may be difficult to conceal, and do not increase penile girth (Jain and Terry, 2006; Montague, 2011). Also, with semirigid rods, the capsule of scar tissue that forms around the device loosens up over time, decreasing the quality of the erection. Because the elastic tunica albuginea wants to retract when stretched to the erect length, the distal tip of the rigid device is more likely to atrophy or migrate toward the distal portion of the glans and potentially to erode through the meatus (see Figs. 30-1 and 30-2).

Inflatable Prostheses

Inflatable prostheses are designed to approximate normal function more closely by permitting girth and length expansion during erection and penile flaccidity when not in use. They consist of two hollow intracorporeal cylinders, each of which fills a corpus cavernosum. The cylinders are inflated with saline solution to produce penile rigidity during sexual activity and are deflated after intercourse. Inflatable prostheses can be subdivided further into two-piece and three-piece devices. The two-piece device consists of the two cylinders and a scrotal pump (Fig. 30-3). Reservoirs in the proximal portion of the cylinders are prefilled with saline and preconnected to the pump via silicone tubing. Pressing a valve mechanism in the pump transfers the solution from the reservoirs into the distal, inflatable portion of each cylinder. Bending the cylinders down for several seconds activates a release valve that deflates the device by allowing the fluid to flow back to the reservoirs. Cylinders are typically available in several widths and lengths to permit a more customized fit. Rear tip extensions allow the length of a two-piece prosthesis to be further tailored to each patient.

The three-piece device consists of the two hollow cylinders, a scrotal pump, and a saline-filled reservoir (Fig. 30-4). Silicone tubing connects the cylinders to the pump and the pump to the reservoir. Repeatedly squeezing the pump transfers saline from the reservoir to the cylinders until adequate rigidity is achieved, and pressing a valve mechanism in the pump causes the fluid to flow back to the reservoir. Similar to the two-piece devices, three-piece devices are also typically available in several widths and lengths and come with optional rear tip extensions. One-touch release models and other more recent innovations in pump design facilitate deflation.

Figure 30-3. Ambicor two-piece prosthesis. (Courtesy American Medical Systems, Minnetonka, MN.)

Figure 30-2. Spectra positional prosthesis. (Courtesy American Medical Systems, Minnetonka, MN.)

Figure 30-4. Coloplast Titan Zero Degree angle cylinders with Touch pump and reservoir with lockout valve prosthesis. (Courtesy Coloplast Corp., Minneapolis, MN.)

An advantage of a two-piece device over a three-piece device is that there is no need to implant a separate reservoir; this facilitates the surgery for the urologist and may be useful with patients in whom placement of the reservoir is extremely difficult because of colostomy, ileostomy, kidney transplant, or extensive pelvic surgery. A two-piece device also reaches full inflation with fewer squeezes of the pump. However, the pump is very small and hard, making it difficult for patients to manipulate. Also, implantation of a two-piece device requires a larger incision of the tunica albuginea. In comparison, a three-piece device acts and feels more like a natural erection. It is more rigid when inflated and is more flaccid when deflated (Fig. 30-5).

Initially, semirigid prostheses were more popular than inflatable devices, primarily because they were easier to implant and rarely required mechanical revision (Wilson and Mulcahy, 2006). However, this preference diminished as mechanical reliability improved. At the present time in the United States, 70% of patients are implanted with three-piece inflatable devices, 20% are implanted with two-piece devices, and 10% are implanted with semirigid rods. Elsewhere, approximately half of all patients are implanted with

semirigid rods, and half are implanted with inflatable devices, primarily owing to cost considerations (Mulcahy and Wilson, 2006).

PREOPERATIVE PATIENT EVALUATION AND PREPARATION

Although penile prosthetic surgery is a highly effective treatment for ED, it is an irreversible procedure accompanied by numerous risks, which makes careful patient evaluation and preparation critical. Thorough preoperative assessment and education can help ensure that a patient is a good candidate for the procedure. It also helps identify the best type of prostheses for any specific circumstance. See Table 30-1 for more details about selection of a prosthesis.

The patient's first visit should be informational in nature; the focus should not be on decision making. It is important that the patient understand the efficacy of the various treatment options available for ED and potential contraindications for penile prosthetic surgery (Box 30-1). Giving a patient the opportunity to

Figure 30-5. A and B, Patient with Coloplast Titan Zero Degree angle cylinders and Touch pump showing the flaccid and erect penis.

TABLE 30-1 Selection of a Prosthesis

CIRCUMSTANCE	RECOMMENDED PROSTHETIC	RATIONALE
Fibrosis (e.g., secondary to priapism)	Narrow-cylinder AMS CXR* or Coloplast Narrow†	Inadequate corporeal space
Peyronie disease/penile curvature	AMS CX*, Coloplast Titan†, or malleable	Allows girth expansion but no length expansion so will not exacerbate curvature
Limited manual dexterity or mentally disabled	Malleable or semirigid rods	Easier to manipulate
Penis length <20 cm	AMS CX*, AMS LGX*, or Coloplast Titan†	Allows for maximum amount of fluid transfer between cylinders and reservoir for best rigidity and flaccidity
Small narrower penis	AMS LGX*	Cylinder lengthens by 18% and narrow corporeal cavity prevents deformity of cylinders on inflation
Abdominoperineal resection Femora-femoral bypass Cystectomy with neobladder	Two-piece device—AMS Ambicor*	Avoids reservoir placement
Extensive abdominal/pelvic surgery Open and post-robotic prostatectomy	AMS Ambicor* or three-piece device—AMS CX or LGX with Conceal Reservoir*	Place reservoir in a submuscular location above the transversalis fascia
Neurologic impairment	AMS CX with soft cylinders	Lower risk of erosion
Atrophic tunica albuginea	AMS CX*	
Older patients with frail tissues and weak hands	AMS CX with Momentary Squeeze Pump*	AMS cylinders are softer, and Momentary Squeeze Pump is easier to deflate
Younger patients with larger, more robust penises	Coloplast Titan with Zero Degree Angle cylinders with Touch pump†	Rounder and wider shaft when cylinders are inflated Smaller, more discreet pump
Penis length >20 cm in length and >21 mm in girth	Coloplast Titan 20, 22 cm or XL 24-28 cm Zero Degree Angle cylinders†	Titan cylinders expand to 22 mm girth vs. 18 mm girth for AMS CX

BOX 30-1 Potential Contraindications for Penile Prosthetic Surgery

Situational ED
 ED resulting from relationship conflict
 Potentially reversible ED
 Inability to follow instructions
 Hygiene issues and skin cleanliness
 Noncompliance with concurrent medication (e.g., for hypertension or diabetes)
 Spinal cord injury
 Uncontrolled diabetes mellitus

ED, erectile dysfunction.

From Garber BB. Inflatable penile prostheses for the treatment of erectile dysfunction: an update. *Expert Rev Med Devices* 2008;5(2):133–44; and Al-Enezi A, Al-Khadhari S, Al-Shaiji TF. Three-piece inflatable penile prosthesis: surgical techniques and pitfalls. *J Surg Tech Case Rep* 2011;3(2):76–83.

handle a sample prosthesis and see how it works facilitates actual use of the device after it is implanted (Bettocchi et al, 2010); however, seeing the entire three-piece device on the first visit can be intimidating and overwhelming. It is best for patients first to see a video and photos of implanted patients to appreciate the look and function of a prosthesis. Next, the patient can be given the opportunity to handle a model of the pump only, without having to handle the reservoir and cylinders. It is important to ensure patients understand that sensation, orgasm, and ejaculatory function are not altered by a penile prosthesis and that nothing is removed to insert the implant. On seeing the device, patients are often concerned about the size of the incision required to implant it, and they should be reassured that only a 1-inch incision is necessary.

A thorough review of the patient's medical, surgical, and sexual history is critical to evaluating the efficacy of previous nonsurgical treatment, selecting the most appropriate type of prosthesis, identifying contraindications, and mitigating risk factors for potential adverse events (Ulloa et al, 2008; Wilson and Mulcahy, 2006). For example, any detected infection should be eradicated before surgery, and glycemic control should be optimized in diabetic patients. Box 30-1 contains a list of potential contraindications for penile prosthetic surgery.

The appointment should also include a complete urologic examination, including a penile Doppler ultrasound study after intracorporeal injection of a vasodilator agent to assess severity of ED, vascular flow, tumescence, and penile anatomy. After a penile injection, the penis is more easily stretched, and abnormalities such as shortening, hourglass deformity, and curvature are revealed and can be evaluated. This is also a good time to measure and record the length of the stretched penis and show the patient what size he should expect from the implant. These measurements can be recorded on a flow sheet and made available during the surgery to confirm that intraoperative measurements of the penis with the cylinders inflated match the measurements obtained in the office.

Finally, informed consent should be obtained from the patient after a discussion that addresses the surgical procedure and postoperative recovery, potential complications (especially complications that may require surgical intervention), and expected outcome. Ensuring that the patient (and, ideally, his partner) has realistic expectations is essential to a positive outcome (Anderson et al, 2007). It is important for the patient to understand that the procedure is irreversible and that positioning the device permanently alters the corpora cavernosa, resulting in the loss of any preexisting erectile capability. Patients should also be made aware that the preoperative length of the fully stretched flaccid

penis is typically the maximal length that can be obtained after prosthetic surgery and that the procedure may result in a degree of penile shortening and glans softening (Montague and Angermeier, 2003).

To help reduce the incidence of postoperative infection, patients are instructed to wash with chlorhexidine soap for 3 days before the surgery. The American Urological Association also recommends preoperative administration of prophylactic antibiotics for both gram-positive and gram-negative organisms for any open procedures involving prosthetic implantation (Wolf et al, 2008). Finally, patients should be instructed to avoid taking aspirin and nonsteroidal anti-inflammatory drugs for 7 days before surgery because such medication can increase the risk of postoperative bleeding. Patients with drug-eluting stents or a history of coronary artery disease are exceptions to this rule and should continue taking low-dose aspirin (81 mg) including on the day of the surgery.

KEY POINTS: PREOPERATIVE PATIENT PREPARATION

- Patients are often concerned about the size of the incision required to implant the device and should be reassured that only a 1-inch incision is necessary.
- It is important the patient understands that the procedure is irreversible and that positioning the device permanently results in the loss of any preexisting erectile capability.
- Patients should know that the preoperative length of the fully stretched flaccid penis is typically the maximal length that can be obtained after prosthetic surgery.
- Ensuring that the patient (and, ideally, his partner) has realistic expectations is essential to a positive outcome.

SURGICAL PREPARATION AND APPROACH

The surgical approach varies depending on the surgeon's preference and on the type of prosthetic device implanted. This section focuses on implantation of a three-piece inflatable device because this type is most commonly used in the United States. The three-piece device can be inserted through a scrotal or infrapubic incision. Each approach offers the surgeon and the patient advantages and disadvantages. Reservoir placement is easier when choosing the infrapubic approach. More precise pump positioning and better cylinder input pump tube concealment are achievable through the scrotal approach, which is described in this section. When planning to implant a standard three-piece device (i.e., 12 to 14 mm), it is recommended also to have a narrower or semirigid device (i.e., 9 to 11 mm) available at the time of surgery; this provides the flexibility to use the narrower option if implanting a multicomponent device becomes difficult because of unanticipated anatomic constraints. For example, it is better to implant a narrower device than attempt vigorous dilation of a fibrotic, scarred corpora and risk urethral perforation. Over time, the narrower device will dilate the corpora, and it may be possible to replace it with a three-piece device 3 to 6 months later.

To the extent possible, it is important to minimize the duration of the surgery, decreasing the risk of infection. This can be facilitated by using a dedicated surgical instrument set that, along with sutures and other necessary equipment, is kept close at hand. The specific instruments, sutures, needles, and cylinder sizes that should be available in the operating room have been described elsewhere (Eid, 2003). It is critical that all instruments are thoroughly scrubbed of all potential debris before undergoing final sterilization. Infection risk is reduced further by using as few instruments as possible and limiting the extent to which they must be passed back and forth with the scrub nurse. Ideally, operating room traffic should be minimized, and laminar flow ventilation should be used to reduce surgical site infection further.

General, local, spinal, or regional anesthesia is administered at the discretion of the anesthesiologist. A benefit of spinal anesthesia

is that it blocks the parasympathetic and sympathetic nervous systems, causing penile dilation and facilitating the surgery. Blood flow to the legs is also increased, which decreases the risk of deep vein thrombosis. A disadvantage of spinal anesthesia is that it necessitates a longer stay in the recovery room and the placement of an indwelling urinary catheter, which needs to be removed within 24 to 48 hours. A risk with general anesthesia is that the typical cough reflex after extubation could potentially herniate the reservoir.

The patient is admitted for a penile implant on the day of surgery and discharged the same day. (Admission to an outpatient surgery center is preferable to hospital admission because the latter increases the risk of cross-contamination from sick patients.) The patient showers before surgery with an antiseptic chlorhexidine scrub and is placed in a supine position on the operating room table. The table should be flexed in a manner that elevates the pelvis and flattens the lower abdomen; this permits a more proximal exposure of the crura and stretches the lower abdominal muscles to provide countertraction for placement of the reservoir. The patient is shaved and undergoes a presurgical chlorhexidine soap scrub of the genital area. The skin is painted with a chlorhexidine/70% alcohol preparation, and intravenous antibiotics are administered to protect against gram-positive and gram-negative organisms, based on the profile of antibiotic-resistant bacteria most commonly found in the institution. An iodophor drape with a small fenestration is used to cover exposed skin while permitting access to the penis and scrotum. A Foley catheter is inserted, capped, and palpated to identify the urethra, which is then avoided for the remainder of the surgery. Finally, a Scott retractor is secured with tubing across the base of the penis. The use of large, blunt yellow hooks instead of the smaller, sharp blue hooks provides better exposure and minimizes the risk of damaging the device or surgical gloves.

From this point forward and depending on the surgeon's preference, it is possible to use a novel "no touch" surgical technique designed to reduce penile prosthesis infection (Eid et al, 2012). With this technique, all surgical instruments used to make the skin incision before cylinder placement are considered contaminated and removed from the surgical field, and everyone on the operating field who has touched skin replaces their surgical gloves (Fig. 30-6).

A study evaluating the no touch technique reported a 0.46% infection rate (Eid et al, 2012). However, regardless of the technique used, exposure of all of the components of the device to the patient's skin must be minimized because most penile prosthesis infections are caused by skin flora that attach to the device and are then introduced into the patient.

Cylinder Placement

A high scrotal approach on the median raphe, approximately 1 inch inferior to the junction with the penis, is preferable to the classic

penoscrotal approach because it allows the incision to be limited to 1 inch, which permits quick closure without scarring and less postoperative bleeding, swelling, and pain. This approach also facilitates access to the penis in obese or thin men. The high scrotal approach is also preferable to an infrapubic approach because the latter increases the tendency of the pump to migrate to a high scrotal position, making it more visible in the anterolateral aspect of the scrotum and leaving the tubing easily palpable at the base of the penile shaft. Scrotal skin is mobilized over the shaft of the base of the penis, and surrounding tissue is pushed laterally by securing the Foley catheter and urethra between the thumb and index finger (see Fig. 30-6).

Dissection can be minimized by making the incision straight down toward the urethra. This incision reduces postoperative swelling and edema and results in a thick layer of subcutaneous tissue allowing for complete isolation of tubing from skin suture line and better incision closure. The scrotal location of the incision also allows for deeper placement and concealment of input tubing to the pump (see Fig. 30-6). A small fenestration is then made in the 3M Steri-Drape 1012 that is placed to cover the operative field and the Scott retractor loosely. Four additional blunt hooks are used to secure the opening in the drape to the edges of the scrotal incision, retracting the cut edges of the skin and drape by securing the hooks on the retractor frame (Fig. 30-7). The remainder of the procedure is performed through the opening, eliminating all direct and indirect contact between the implant and the skin.

The tunica albuginea of each corpus cavernosum is identified on either side of the urethra (Fig. 30-8), secured with 3-0 polydioxanone suture (PDS) RB-1, and incised 1 cm lateral to the urethra (Fig. 30-9). The incision should be limited to the tunica albuginea and avoid cavernosal muscle tissue. Positioning the corporotomy close to the urethra allows direct downward orientation of the tubing between the cylinder and the pump and makes it less likely that the patient will be able to palpate the tubing at the base of his penis.

Blunt scissors are used to develop a space between the tunica albuginea and cavernosal muscle (Fig. 30-10) in both directions to

Figure 30-6. Securing the Foley catheter and urethra.

allow sequential dilation of the corpora using Dilamezinsert (Lone Star Medical Products, Stafford, TX) or Hegar dilators. More than half of surgery-related complications when implanting cylinders occur during this part of the procedure (Henry and Wilson, 2007). The use of force is unnecessary and should be avoided to prevent perforation of the tunica albuginea and damage to the urethra at the meatus or the crus, which can occur during either distal or proximal dilation (Sadeghi-Nejad, 2007). The use of special dilators (e.g., Rossello [Coloplast Corp., Minneapolis, MN] or Uramix [Uramix, Inc., Lansdowne, PA] double-blade cavernotome dilators or Otis urethrotome) can help decrease the risk of perforation in the presence of corporeal fibrosis (Bettocchi et al, 2008).

To prevent distal or proximal crossover into the contralateral corpus during initial dilation, constant traction should be applied to the shaft of the penis by pulling on the glans, and the curvature of the scissors should be maintained away from the midline of the penis, with the tips next to the tunica albuginea (see Fig. 30-10). It is preferable to dilate at the level of the venous plexus at

Figure 30-10. Initial dilation with blunt-tip Mayo curved scissors.

the periphery of cavernosal muscle tissue (vs. centrally through cavernosal muscle). If crossover occurs, it is usually preferable to recognize it and correct it during this part of the procedure, rather than after further dilation or insertion of the cylinders.

To correct a distal perforation, the damaged corpus apex should first be exposed through a transverse incision of the skin and tunica albuginea near the glans. A small hole can usually be located distally on the medial aspect of the cavernosal cavity and repaired using separate PDS stitches. The distal apex of the corpora needs to be closed with a second running suture, and a slightly shorter prosthetic cylinder is selected for the perforated side; this is necessary to prevent the distal tip of the cylinder from resting on the urethral suture repair. A more conservative approach would be to terminate the procedure and bring the patient back for implantation 3 months later. The disadvantage of this strategy is that the length of the shaft is foreshortened, and dilation of the scarred corpora is much more difficult. If the perforation occurs after both corpora are dilated, a semimalleable cylinder can be placed in the nonperforated side to preserve penile length. Use of a Dacron or Gore-Tex sleeve should be avoided because of the markedly increased risk of infection and ingrowth into the graft, which makes it impossible to remove. To evaluate proximal perforation during surgery, a dilator can be placed in each crura, and their heights can be compared to confirm that one has penetrated too deeply inside the perineum. Repair involves anchoring the cylinders to the surrounding corpora tissue by placing stitches above and below the input tubing, which prevents the cylinder from proximal migration and allows the perforation to heal. Alternatively, nonabsorbable sutures can be used to create a sling through the solid portion of the inflatable cylinder (Bettocchi et al, 2008). A study comparing prosthetic implantation with or without corpora dilation suggested that dilation is unnecessary in primary implantation cases. The investigators reported that patients receiving an implant without the use of dilation experienced less postoperative pain and increased penile length compared with patients in whom dilators were used to facilitate cylinder insertion (Moncada et al, 2010).

To select an optimally sized cylinder, the corporeal lengths should be measured distally and proximally with respect to a fixed

Figure 30-11. Dilamezin insert is used to obtain distal measurement.

Figure 30-12. Furlow introducer is used to pass right cylinder traction suture.

point of reference, such as a traction suture (Fig. 30-11). Oversized cylinders can result in erosion and an S-shaped penile deformity, which can cause increased wear at the flexion point of the curve and lead to mechanical failure (Wilson et al, 1996; Montague, 2011). Conversely, an undersized cylinder may not adequately support the glans; this can be easily addressed by adding rear tip extenders. It is important not to overstretch the penis over the measuring instrument, especially when measuring the proximal portion. Creating an artificial erection by irrigating the corpora with saline can help assess if the penis is straight or curved. Noting the presence or absence of irrigant leakage from the meatus around the catheter can also help evaluate the possibility of urethral injury.

When a cylinder is selected, the device is opened on the surgical field and prepared for implantation by purging air from the cylinders and pump. The traction suture from the distal tip of each cylinder is secured to a Keith needle and passed into the distal aspect of the penile shaft and through the glans penis with the Furlow introducer (Fig. 30-12).

Damage to the device is avoided by passing both sutures and Keith needle before placing a cylinder into a corpora (Bettocchi et al, 2010). Because most cylinders are preconnected to the pump, it is important to orient the cylinders such that the two input tubes to the pump do not cross over each other. After each traction suture has been passed through the glans penis, the proximal portion of each cylinder is inserted first. The cylinder is folded on itself, and when the distal tip is placed in the corporeal orifice, the traction suture is pulled to insert the rest of the cylinder.

Each cylinder must lay flat in the corpora when traction is applied on the suture. Any folds observed in the cylinder indicate that it may be too long or that the rear tip is not properly positioned.

When both cylinders have been inserted, a 60-mL syringe filled with saline is used as a surrogate reservoir to inflate the cylinders to evaluate erection size and quality. The cylinders are then deflated, and the penis is reexamined to ascertain correct cylinder sizing. This test can also help identify cylinder malfunction or damage should it occur. If the cylinder length needs adjustment, the saline should

Figure 30-13. Watertight closure of right corporotomy.

be completely removed from the cylinder before removing the cylinder from the corpora and changing or removing the rear tip extender; this facilitates the adjustment and decreases the chance of damaging the cylinder. Each time a cylinder is removed, adjusted, and repositioned into the corpora, it can become contaminated and its sterility can be compromised, especially if it comes into contact with skin.

A watertight closure of the corporotomy can be achieved with a running 3-0 PDS using a hemostatic stitch or by approximating the previously placed tagging 3-0 PDS (Fig. 30-13). Although the former

approach takes more time and can potentially cause needle injury to the cylinder, it is preferable because it creates a watertight closure. When the corporotomy is closed, the pump should be activated and deactivated several times while assessing cylinder size and integrity. **If the latter approach is used, and a watertight closure is not achievable, a drain should be placed at the end of the procedure to evacuate bleeding and prevent scrotal hematoma.**

Pump Placement

Placement of the pump before the reservoir minimizes skin contact time while the reservoir is being placed. Allis clamps are used to provide gentle traction to the scrotal fascia, and a flap is developed beneath the urethra for a distance of 2 to 3 cm. A long, closed nasal speculum is introduced into a 1-cm incision made in the scrotal fascia, approximately 1 to 2 cm from the urethra, and directed upward between both testicles and toward the bottom of the scrotum. The speculum is used to form a pocket in the scrotal sac, in the fatty layer between the testicular tunica vaginalis and slightly behind the testicles (Fig. 30-14).

It is important to keep the blades of the speculum closed until the tips reach the bottom of the scrotal sac to prevent excessive dilation of the pouch, which should fit snugly around the pump. This prevents posterior pump migration, which renders it less accessible to the patient. **The pump should be positioned such that the deflation footprint is easily accessible to the patient yet unobtrusive, and the tubing between the pump and the cylinders should be placed so that it cannot be detected by the patient and sexual partner.** After obtaining complete hemostasis, the opening in the scrotal fascia can be closed. Bleeding around the pump causes an inflammatory reaction and hematoma formation, and a thick capsule develops around the pump. Use of the implant is delayed, and it is difficult to activate the device.

Reservoir Placement

Before reservoir placement, it is important to ensure the bladder is empty to avoid bladder perforation. While applying upward traction to the penis, the base of the crus is palpated, and Scarpa fascia is bluntly divided. In this manner, a defect is created between the crus of the penis medially and the spermatic cord laterally. Next, the operator's finger is oriented toward the pubic ramus, and the external inguinal ring is identified. The tip of a large blunt Mayo curved scissors is placed over the pubic ramus by sliding it between the base of the penis and the operator's finger. After tilting the scissors at a 90-degree angle with the plane of the abdominal wall and positioning the tip of the scissors just over the pubic ramus, a small 0.5-cm defect is made in the floor of the inguinal canal with the

blunt Mayo scissors. **It is important to limit the excursion of the scissors to a 1-cm depth and to maintain the scissors on the pubic ramus.** Incomplete perforation of the floor of the inguinal canal should be avoided because it will cause separation of transversalis fascia from the undersurface of the internal oblique muscle. This will cause a decrease in the countertraction of the transversalis fascia, making it more difficult to puncture the floor of the inguinal canal and access the space of Retzius. When the defect of the floor is made, the scissor is removed and exchanged for a nasal speculum with 8-cm-long blades (Fig. 30-15). **It is unnecessary to dilate the space of Retzius vigorously, and great care must be taken not to make a large defect in the floor of the inguinal canal resulting in reservoir herniation or migration.**

This part of the procedure may be difficult in a patient after hernia repair and transversalis fascia thickening owing to mesh and previous surgery. In such cases, it may be necessary instead to make a separate incision for adequate reservoir placement or to implant the reservoir in a submuscular location. The latter approach may make the reservoir palpable and possibly visible (Henry and Wilson, 2007; Al-Enezi et al, 2011). Catastrophic outcomes, such as injury to bowel or a major blood vessel or placing the reservoir into the bladder, colon, and vena cava, have occurred in the past when attempting to place the reservoir in this manner in patients with previous pelvic surgery. **Placement of the reservoir in the space of Retzius should be performed only in patients who have not undergone surgery previously.** Submuscular reservoir placement with a flat reservoir (AMS Conceal; American Medical Systems [AMS], Minnetonka, MN) or a separate incision (Fig. 30-16) should always be performed in all patients after robotic prostatectomy, radical cystectomy, and abdominoperineal resection and in patients with history of pelvic fracture with bladder rupture and pelvic surgery. However, positioning the reservoir above the transversalis fascia in a submuscular position can lead to autoinflation of the device, which occurs when the fluid pressure within the reservoir is greater than the back-pressure limits of the pump (Levine and Hoeh, 2012).

When the space of Retzius is entered with the long nasal speculum, it is opened, and the surgeon's index finger is used to confirm

Figure 30-14. Placement of pump into scrotal sac.

Figure 30-15. Placement of reservoir into space of Retzius.

its position. An empty reservoir is placed through the nasal speculum next to the bladder, the speculum is removed, and the reservoir is filled with the appropriate amount of saline. A back-pressure test performed by applying gentle pressure on the lower abdominal wall. A palpable reservoir or back-pressure of saline noted into the syringe is an indication that it has not been properly positioned. A surrogate test should then be performed, using a syringe as the reservoir, to confirm proper reservoir placement and check for back-pressure. It is important that the prosthesis is completely deflated before tubing from the pump is trimmed and connected to tubing from the filled reservoir. **Every effort must be made to maintain the reservoir full during the immediate postoperative period to prevent autoinflation of the device later on.** Allowing healing to occur over a partially filled reservoir limits its ability to store an adequate volume of saline. If hematuria is present at this point, it could potentially indicate injury to the bladder wall, which must be ruled out before closing.

Closure

At this point, the surgical site should be irrigated and reexamined for hemostasis. When hemostasis is confirmed, Buck fascia and the dartos muscle are closed, followed by closure of the skin. A benefit of using nonabsorbable sutures are the warm baths (lying flat, not sitting) started on postoperative day 3, which help relieve pain, decrease any swelling or edema, and keep the scrotum clean. The catheter can be removed the morning after the surgery by the patient at home, and the stitches are removed after 14 days.

The use of a closed-suction drain to reduce the risk of hematoma after inflatable penile implant surgery is controversial. Two retrospective studies investigating the use of drains did not produce conclusive results, and there have been no randomized controlled clinical trials evaluating the efficacy of using a drain after implant surgery (Wilson et al 1996; Sadeghi-Nejad et al, 2005; Kramer et al, 2011). Proponents posit that draining the scrotum can decrease edema, increase comfort, and decrease the time to initiation of device cycling. Opponents argue that draining increases the risk of infection, drain fracture, bleeding during placement, and damaging the device and inconveniences the patient, who then has to return to the clinic the following day to have the drain removed (Sadeghi-Nejad et al, 2005; Kramer et al, 2011). A review of articles addressing penile prosthetic infection published in Medline and EMBASE

databases from 2000 to 2012 concluded that no recommendation can be made about the use of surgical drains to reduce infection rates associated with penile prosthetic surgery (Elmussareh et al, 2013). **If the surgeon is not satisfied with hemostasis, the surgical area should be drained.**

KEY POINTS: SURGICAL PREPARATION AND APPROACH

- Minimizing surgery duration decreases the risk of infection.
- Exposure of all of the components of the device to the patient's skin should be minimized.
- During dilation, the use of force is unnecessary and should be avoided to prevent perforation of the tunica albuginea.
- Narrower inflatable and semirigid devices should be available for all cases in the event that implanting a three-piece device becomes difficult.
- Placement of the reservoir in the space of Retzius should not be performed in patients with prior pelvic surgery.
- A closed-suction drain should be used if the surgeon is not satisfied with hemostasis.

POSTOPERATIVE CARE

When implanting a penile prosthesis, the outcome is very dependent on the nature of postoperative care. Because the surgery is typically an outpatient procedure or involves a 23-hour stay, the Foley catheter and drain (if used) are removed the morning after surgery (Garber, 2008). The efficacy of postoperative prophylactic antibiotics has not been demonstrated in prospective studies and remains controversial. Although there is no consensus regarding the type or duration of antibiotic administration postoperatively, a survey of 216 urologists found that most prescribed antibiotics for 7 days after surgery and favored quinolones (Koves et al, 2011; Wosnitzer and Greenfield, 2011; Elmussareh et al, 2013).

During the first week, the patient should avoid sitting on the scrotum (this can push the pump upward) and lifting more than 15 pounds or any other activities that could cause displacement of the reservoir into the inguinal canal. **Brief-style underwear should be worn for the first month, with the penis placed on the lower abdomen and oriented toward the umbilicus until the device is first inflated.** Such positioning promotes capsule formation around the cylinders and will orient the erection in an upward direction. It also helps prevent downward curvature during the healing process (Wilson and Mulcahy, 2006; Montague, 2011).

If the type of device implanted does not include a lock-out valve on the reservoir, the patient should be warned about the potential for postoperative autoinflation, which typically occurs following intra-abdominal pressure increase. This autoinflation can be embarrassing and increases the risk of cylinder erosion (Abbosh et al, 2012). Should autoinflation occur, the patient may need to return to the clinic earlier than usual for instruction about how to deflate the device. At 3 months, the capsule that forms around the reservoir typically protects it from any pressure increase and decreases the incidence of autoinflation (Wilson and Mulcahy, 2006). **It is important for the patient to understand that capsule formation should occur when the reservoir is full, and the reservoir should not be left in a partially filled state for extended periods.** If the capsule forms around a partially filled reservoir, the capsule will restrict future expansion of the reservoir, prohibit complete cylinder emptying, and potentially cause autoinflation, resulting in a need for surgical revision. Abbosh and colleagues (2012) described the use of outpatient laparoscopic capsulotomy to treat this problem.

The extent to which a patient experiences postoperative pain varies depending on his tolerance and any preexisting conditions (e.g., neuropathy). Scrotal bruising and swelling are common, with

scrotal hematoma typically receding without surgical intervention (Wilson and Mulcahy, 2006). An oral narcotic is often required the first week, followed by nonsteroidal anti-inflammatory medication as needed. Ice packs may be used intermittently.

The first postoperative visit typically occurs at 2 weeks to assess wound healing and manage any signs of autoinflation. During this visit, it is critical to identify early signs or symptoms of local infection. The patient again returns to the clinic at approximately 4 weeks after surgery for an appointment focusing on how to operate the device. Initial inflation of the prosthesis may be difficult, and the patient should be instructed to cycle the device (i.e., inflate and deflate it) during warm baths twice each day for the next month to facilitate its use. The patient can then attempt sexual intercourse as soon as he feels comfortable using the device. Additional postoperative instructional visits may be necessary, depending on each patient's experience. Subsequent follow-up at 3 months, 6 months, and then annually should be scheduled to assess healing, particularly cylinder tip position in the glans; device functioning; and patient satisfaction.

COMPLICATIONS

Complications can occur during surgery or postoperatively. Complications that can occur during surgery include organ injury/perforation, cylinder crossover, and damage to the device during implantation. These are addressed in Surgical Preparation and Approach. Complications that can occur postoperatively are addressed in the following sections.

Infection

Infection is a serious complication of prosthetic surgery and represents significant pain and suffering for an elective procedure. The incidence of infection is estimated to be approximately 4% for primary implants before the introduction of specially coated devices and 10% for revision implants (Henry et al, 2004); however, this may reflect underreporting because of discontinuity of care (Muench, 2013). Research suggests that most infections are caused by bacteria on the skin that attach to the device and are then introduced into the patient. Because infections are infrequent and evidence suggests that skin bacteria are relatively innocuous, physicians tend to assume that such contamination is inevitable and focus their efforts on managing the contamination by irrigating, using antibiotic-coated implants, and administering IV antibiotics (Henry et al, 2008; McKim and Carson, 2010), overlooking surgical technique (i.e., avoiding touching the skin) as an adjunct to decrease the potential source of infection further.

Knowing the time line of presentation of a suspected infected prosthesis can help guide early management and diagnosis. For example, at the 2-week postoperative interval, if the patient does not seem to improve and reports persistent or increased pain, one must resist the temptation to prescribe oral antibiotics. If the device is not infected, the patient should experience a clinical improvement within the next 7 to 14 days. If the device is infected, antibiotics are useless at this point and may delay diagnosis. Fever, erythema, swelling, elevated white blood cell count, and incision drainage are late signs and symptoms of infection and are usually not observed at this postoperative visit. The sooner an infection is diagnosed, the better the chance for successful salvage. Imaging studies such as scrotal sonography, computed tomography scan, and magnetic resonance imaging are not helpful in making an early diagnosis. Tethering of the pump may also be a sign of infection but can sometimes be caused by inflammation and capsule formation from a hematoma. Capsule formation improves over time, whereas inflammation persists or becomes more pronounced. Close patient follow-up and weekly examinations with evaluation of white blood cell count are important when an infection is suspected. Clinical deterioration with persistence of pain and tethering at 3 to 4 weeks postoperatively signals an infection, and aggressive early salvage should be considered before systemic symptoms,

Figure 30-17. Tethering of pump consistent with early infection of prosthesis.

such as fever, elevated white blood count, erythema, and abscess formation of scrotum, occur (Fig. 30-17).

The bacterial contamination that causes infection most often occurs at the time of surgery and typically involves organisms that colonize the skin, such as *Staphylococcus epidermidis*, *Staphylococcus aureus*, and *Candida albicans*. These organisms can persist despite perioperative antibiotics. When they reach a critical mass, they excrete a biofilm in which they can live in a decreased metabolic state, causing no clinical symptoms until at least 4 to 6 weeks and sometimes years after implantation (Wilson and Mulcahy, 2006). Because of the biofilm, the use of systemic antibiotics to treat symptomatic patients is typically insufficient, and infection necessitates the removal of all device components as well as any permanent sutures or graft material used during corporeal reconstruction. Attempts to remove only part of an infected device typically result in persistent infection (Garber, 2008).

Traditionally, after removal of an infected implant, a surgeon waited several months before considering replacement. However, severe cavernosal fibrosis after explantation complicates replacement surgery, contributing to a 50% success rate even for experienced surgeons. The fibrosis also causes significant penile shortening and potential loss of sensation, which has a negative impact on patient satisfaction (Muench, 2013). Introduction of a "salvage" procedure involving removal of the infected prosthesis, wound washout, and immediate device replacement helped facilitate reimplantation and preserve penile length (Brant et al, 1996; Jain and Terry, 2006). When indicated (i.e., for chronic and nonpurulent infection), salvage success rates can exceed 84% if the procedure includes thorough wound irrigation with a series of antibiotic and antiseptic solutions, followed by a change of surgical gowns, gloves, drapes, and instruments; placement of a new device; wound closure without drains; and oral antibiotics for 1 month (Mulcahy, 2000; Henry et al, 2005; Garber, 2008). More recent research suggests that aggressive washout with normal saline combined with meticulous sterile technique may further improve postsalvage infection and reoperation rates (Masson, 2012). The salvage technique can also

be used when a device requires replacement for reasons other than infection (Henry et al, 2005). Salvage is contraindicated in patients presenting with enterococcus, tissue necrosis, sepsis, diabetic ketoacidosis, or cylinder erosion into the urethra (Mulcahy 2003; Wilson and Mulcahy, 2006).

When malfunctioning penile prostheses are removed, they are often found to be colonized with pathogenic bacteria, even in the absence of clinical infection. For example, Silverstein and colleagues (2006) used scanning laser microscopy to determine that 80% of prostheses explanted because of mechanical malfunction were colonized with gram-positive rods, cocci, and fungal elements, and Henry and associates (2004) reported that culture-positive bacteria were found in 70% of patients with clinically uninfected penile prostheses. However, according to a study by Kava and colleagues (2011), less than 10% of devices removed because of malfunction or rerouted because of extrusion were colonized with pathogenic bacteria. The authors also found that there was no correlation between culture-positive patients and postoperative infection. They suggested that their findings may differ from findings of other investigators because of their use of a preoperative, adjuvant, alcohol-based skin preparation.

More recently, a novel surgical technique has been developed to facilitate delayed implantation of a replacement device. Swords and coworkers (2013) described the insertion of a temporary filler consisting of an antibiotic cast of synthetic high-purity calcium sulfate into the corpus cavernosum when an infected device is removed. This “spacer” provides constant delivery of local antibiotic to the infected area and reabsorbs within 30 to 60 days, at which time a new prosthetic device can be implanted.

Specially coated three-piece devices have been developed by both AMS (Minnetonka, MN) and Coloplast Corporation (Minneapolis, MN) to inhibit bacterial adhesion and proliferation. The AMS 700 devices are impregnated with InhibiZone, a coating on the external surface of the device that elutes rifampin and minocycline to inhibit bacterial growth. The Coloplast Titan prosthesis has a hydrophilic polyvinylpyrrolidone coating that absorbs and elutes any antibiotic solution in which it is soaked. The introduction of these coatings within the past decade has decreased the incidence of infection by 50% to 70%, even after 11 years of follow-up (Carson et al, 2011; Mandava et al, 2012; Serefoglu et al, 2012). This decreased incidence confirms our hypothesis that infections are caused by contamination of the prosthesis at the time of implantation. It appears that the antibiotics eluting from the devices and/or the slippery surfaces of the implant reduce the proliferation and attachment of the relatively milder, late-appearing types of bacteria noted earlier. However, although such coatings have significantly decreased overall infection rates, more aggressive and earlier-appearing bacteria, such as *Enterococcus*, *Escherichia coli*, and *Pseudomonas aeruginosa*, are now causing infection at increasing rates (Eid et al, 2012).

Risk factors for infection may be related to patient history, intraoperative conditions, or postoperative variables. Risk factors related to patient history include poor patient hygiene, spinal cord injury, urinary tract infection, distant sites of infection, and revision surgery performed for previous device infection; however, it is unclear whether revision surgery for mechanical failure is associated with higher rates of infection (Cakan et al, 2003; Kava et al, 2011; Selph and Carson, 2011; Elmussareh, 2013; Muench 2013). Diabetes mellitus may also be a risk factor, although studies report conflicting results. For example, a large retrospective study with a follow-up period of up to 7.7 years found a higher incidence of first revisions owing to infection in diabetic patients compared with nondiabetic patients; however, other studies have not found a difference in the incidence of infection between the two groups (Lotan et al, 2003; Mulcahy and Carson, 2011). It is also unclear whether poorly controlled diabetes and immunosuppression are associated with an increased infection risk (Bishop et al, 1992; Wilson et al, 1998; Elmussareh et al, 2013). Intraoperative risk factors for infection may include inadequate skin preparation with alcohol/chlorhexidine; prolonged surgical time (i.e., >2 hours); prolonged and repeated exposure of components of the

prosthesis to patient’s skin; frequent repositioning and resizing of the cylinder, pump, or reservoir; scrotal hematoma (particularly if liquefied); and not changing gloves before handling the device. A postoperative variable associated with infection risk is prolonged hospitalization.

A review of studies focusing on penile prosthetic infection between 2000 and 2012 suggested that the most important factors to minimize the risk of device infection include the use of antibiotic-coated prostheses and procedures that decrease inoculating bacteria into the surgical wound (i.e., alcohol skin preparation, a no touch surgical technique, and perioperative antibiotic use) (Elmussareh et al, 2013). Although the use of perioperative antibiotics reduces infection, there are no specific guidelines recommending antibiotic protocols, and a wide range of practice patterns exists among urologists performing prosthetic surgery (Wosnitzer and Greenfield, 2011).

KEY POINTS: INFECTION

- Knowing the time line of presentation of a suspected prosthetic infection can help guide early management and diagnosis.
- Infection necessitates the removal of all device components as well as any permanent sutures or graft material used during corporeal reconstruction.
- Factors that minimize the risk of device infection include the use of antibiotic-coated prostheses and procedures that decrease inoculating bacteria into the surgical wound (i.e., alcohol skin preparation, a no touch surgical technique, and perioperative antibiotic use).

Device Malfunction

Device malfunction is becoming less common as prosthesis design improves over time (Bettocchi et al, 2010). A historical prospective study estimating long-term survival rates of first-time implants (N = 2384) found that freedom from mechanical breakage was 79.4% at 10 years and 71.2% at 15 years (Wilson et al, 2007). The most common types of malfunction in a three-piece prosthetic device depend on the manufacturer and include cracks in the silicone tubing, leaks at the site where the tubing connects to the pump, leaks within the cylinder, cylinder aneurysm, and pump disruption (Garber, 2008). Autoinflation, which is discussed elsewhere in this chapter, has been observed to occur in 2.4% to 11% of devices overall, but this incidence decreased to 1.3% in devices with lock-out valves (Carson et al 2000; Wilson et al, 2002). Reservoir-related mechanical malfunction is also rare, and it is unclear whether a functioning reservoir should be replaced during revision surgery to address other issues (Levine and Hoeh, 2012).

If malfunction occurs within a few months after implantation, replacement of only the defective component should be considered, especially if this avoids a repeat corporeal incision. After the device has been in place for more than 2 years, complete replacement is indicated (Jain and Terry, 2006). Other options following malfunction include no treatment or device removal without replacement. When choosing the latter, it is important for the patient to understand that because the cavernosal space is now empty, the tunica albuginea will retract, scar tissue will form inside the penis, and the penis will become permanently shorter.

Other Complications

Postoperative complications occurring less frequently than infection and device malfunction include erosion, S-shaped penile deformity, poor glans support, and scrotal hematoma. Erosion typically occurs months or years after implantation and can manifest in several different locations. For example, an oversized cylinder, especially the semimalleable type, is most likely to erode into the

meatus at the level of the glans. The pump and input tubes to the cylinders can erode at the level of the scrotal skin if placed too superficially, although an indolent low-grade bacterial infection is most often the reason for this (Natali, 2010; Talib et al, 2013). Similarly, the reservoir can erode into the bowel or bladder if either is fixed in place by adhesions resulting from previous surgery or radiation; however, this is very uncommon (Levine and Hoeh, 2012). **Regardless of the location, erosion always necessitates complete removal of all the components of the device and possible salvage replacement.** If only one of the cylinder tips has eroded through the meatus, the entire device needs to be removed, including the pump and reservoir, and a malleable cylinder is placed in the noneroded side only, to prevent shortening of the penis. The perforation must be allowed to heal for 8 to 12 weeks before reimplantation is attempted (Natali, 2010).

An S-shaped penile deformity can occur after incomplete distal dilation of the corpora cavernosa and/or implantation of an oversized cylinder (Wilson et al, 1996; Bettocchi et al, 2008). This complication also necessitates device replacement. In contrast, implantation of an undersized cylinder can result in poor glans support; however, this can be treated by adding rear tip extenders or by replacing the cylinders with the correct size without disturbing the scrotal pump.

Because blood collects in dependent areas of the body, scrotal hematoma can follow implantation of a three-piece prosthesis, with reported incidence ranging from 0.7% to 3.6%. Attempts to decrease the development of scrotal hematoma include keeping corporotomies small, closing with a running watertight suture, and using hemostatic sealant (Cohen and Eid, 2014). Kramer and colleagues (2011) published an analysis of the risks and benefits related to the use of closed-suction drains. In the absence of a large, prospective, randomized trial, it is unclear which course of action is most beneficial, and the final decision is largely a matter of surgeon preference. **In my opinion, it is better to use a drain than to risk hematoma. Blood in the scrotal sac causes significant inflammation and formation of a thick fibrous capsule around the pump, which makes it very difficult for the patient to manipulate the pump when healed.** Additionally, a liquefying hematoma provides iron and nutrients, making it an ideal setting for bacterial growth and infection.

SPECIAL CASES

Several situations make implantation of a penile prosthesis particularly challenging. These include previous pelvic surgery (which is addressed in Surgical Preparation and Approach), Peyronie disease, priapism, scleroderma and lupus, and previous radical prostatectomy.

Peyronie disease is characterized by focal fibrotic replacement of healthy tunica albuginea; this most commonly causes curvature of the penis toward the location of the scar and results in ED (Mulcahy and Wilson, 2006). A prosthetic implantation procedure similar to that described in Surgical Preparation and Approach has been found to straighten the erection adequately in approximately 40% of patients (Chaudhary et al, 2005). Otherwise, penile straightening may be required and typically involves manual modeling during which the tunical plaque is fractured over an inflated cylinder at the time of implantation by forcibly bending the penis in a direction opposite the curvature. Plication or tunical incision/excision with or without grafting may rarely be necessary (Hudak et al, 2013; Segal and Burnett, 2013). Mulhall and associates (2005) developed an algorithm for the surgical treatment of Peyronie disease and ED that involves objective assessment of penile deformity using dynamic infusion cavernosometry and cavernosography, followed by administration of erectogenic therapy. The authors found that patients who did not respond to erectogenic therapy and underwent penile prosthetic surgery had excellent results. Other studies subsequently reported that surgical placement of an inflatable penile prosthesis is an effective treatment option for Peyronie disease (Levine et al, 2010; Chung et al, 2013). However,

another study suggested that Peyronie disease compromises inflatable prosthetic device durability and increases malfunction rates, possibly owing to stress on the device during surgery, use, or both (DiBlasio et al, 2010).

Priapism is defined as a full or partial erection that continues for more than 4 hours beyond intercourse or is unrelated to sexual stimulation (Tausch et al, 2013). If left untreated, the resulting fibrosis is usually distal, extensive, and dense, making it very difficult to dilate with conventional instruments (Wilson and Mulcahy, 2006; Martinez-Salamanca et al, 2011). A review of surgical procedures to facilitate prosthetic implantation and improve outcomes in such situations suggests that scar incision should include a combination of techniques (i.e., extensive wide excision, multiple incisions minimizing excision, corporeal counterincisions, corporeal excavation technique, or Shaeer technique) as well as cavernotomies and smaller prostheses (Shaeer and Shaeer, 2007; Martinez-Salamanca et al, 2011). A retrospective analysis of prosthetic implantation in 17 patients with postpriapism ED found that although all patients were successfully implanted without major postoperative complications, 2 patients experienced urethral injury secondary to extensive corporeal fibrosis (Durazi and Jalal, 2008).

The use of radical prostatectomy to treat prostate cancer often results in ED. Some clinicians assume that implantation of a three-piece prosthetic device is contraindicated in such situations because of a perceived increased risk of intraoperative injury. To address these concerns, two studies investigated the use of penile prostheses after radical prostatectomy. In the first, Lane and colleagues (2007) reported that of 115 consecutive patients receiving a three-piece inflatable penile prosthesis after prostatectomy, none experienced intraoperative complications, including injury to the bladder or iliac vessels, with successful blind entry into the retropubic space in all cases. In the second study, Menard and associates (2011) examined surgical complication and patient satisfaction rates in subjects receiving a penile implant after radical prostatectomy and found that the procedure was associated with low morbidity and high satisfaction, especially with respect to erectile function; however, they noted that fibrosis in the retropubic space may necessitate a second incision for reservoir placement or use of a two-piece device instead of a three-piece device. Nevertheless, there have been several catastrophic mishaps related to implantation of a penile prosthesis after prostatectomy, such as placing the reservoir in the bladder, sigmoid colon, or vena cava and injury to the bladder or bowel. **In my opinion, the reservoir should always be placed through a separate incision (if the implant is performed via a penoscrotal approach) and placed in a submuscular position.** Although robotic prostatectomy can be performed through an extraperitoneal approach, most prostatectomies are performed transabdominally, and the peritoneum is not closed after the prostate is removed. Under this circumstance, a second incision (preferably on the right side to avoid the sigmoid) or submuscular reservoir placement must always be performed.

PATIENT SATISFACTION

In general, patient satisfaction with penile prosthetic implantation for ED has increased over the past 40 years, seemingly at least partly as a result of mechanical and design enhancements (Trost et al, 2013). **Patient satisfaction with penile prosthetic implantation is currently the highest among all of the treatments for ED** (Mulcahy, 2010; Rajpurkar and Dhabuwala, 2003). Bernal and Henry (2012) reviewed all relevant research published over the past two decades and identified nine studies meeting their inclusion criteria (e.g., >30 subjects, three-piece device, written in English), all of which indicated that patients report high satisfaction rates. This seems to be the case regardless of device manufacturer or older age (Brinkman et al, 2005; Villarreal and Jones, 2012; Chung et al, 2013).

In a study designed to identify specific factors that affect overall satisfaction, 21 patients were surveyed preoperatively about their

expectations and asked to rate their satisfaction 4 months postoperatively (Kramer and Schweber, 2010). The investigators found an inverse correlation between patients' expectations and postoperative satisfaction, suggesting that helping patients have realistic expectations and providing them with an accurate description of the procedure result in higher satisfaction after implantation.

Factors associated with postoperative dissatisfaction include a diagnosis of Peyronie disease, a history of radical prostatectomy, and a body mass index of 30 (Akin-Olugbade et al, 2006). The most common postoperative complaint associated with the reduction of overall satisfaction is loss of penile length (Lee and Brock, 2013). Strategies to preserve penile size after prosthetic implantation can be implemented before insertion, intraoperatively, or after insertion. Henry and colleagues (2012) conducted a prospective, multicenter study to assess patient satisfaction and axial rigidity of a cylinder that is longer in length than other available prostheses. The investigators concluded that the longer cylinders had great rigidity based on objective and subjective assessment. They also reported that patients had excellent satisfaction rates after implantation of the longer cylinders.

CONCLUSION

Penile prosthetic surgery is a highly effective treatment option for patients with ED who fail first-line and second-line therapy. Over the past 40 years, refinements in surgical technique have

significantly reduced the rates of infection and other complications, and innovations in prosthetic design have had a positive impact on device malfunction rates. High levels of patient and partner satisfaction exceed that of many other, less invasive treatment options and reflect the fact that penile implants have become the "gold standard" for the treatment of advanced ED.

Conclusion

GENERAL CONSIDERATIONS

Peyronie disease (PD) was first known as *induratio penis plastica*. It was subsequently named after Francois Gigot de la Peyronie because he was the first to describe and offer treatment for it in a paper published in 1743 (Peyronie, 1743). But Guilielmus de Saliceto in the 13th century and Gabriele Falloppio in the 15th century had previously reported on this abnormality of the penis (Musitelli et al, 2008).

PD is currently recognized as a wound-healing disorder of the tunica albuginea (Devine and Horton, 1988) that results in the formation of an exuberant scar, occurring presumably after an injury to the penis activates an abnormal wound-healing response (Van De Water, 1997; Greenfield and Levine, 2005; Ralph et al, 2010; Levine and Burnett, 2013). The resulting scar or plaque is inelastic and therefore results in penile deformity including curvature, indentation, hinge effect, and shortening and is frequently accompanied by erectile dysfunction (ED). One of the most important characteristics of this particular wound-healing disorder is that once the scar has occurred, it does not undergo normal remodeling and therefore the scar and deformity persist (Del Carlo et al, 2008). Progress with treatment of PD has been limited by an incomplete understanding of its pathophysiology, and this lack of understanding has resulted in an inability to prevent the disease from starting and to prevent progression once it has occurred. This, combined with the fact that there is no known reliable treatment to reverse the scarring process, makes PD a challenging disorder to treat.

Multiple misconceptions have been held for decades about PD. Many of these misconceptions have been carried forward and appear to have compromised the proper assessment and early treatment of men with PD (LaRochelle and Levine, 2007). These include that Peyronie is a rare disorder. On the contrary, we now know that the prevalence of PD is somewhere between 3% and 20%, and in certain populations such as those with diabetes mellitus and ED the prevalence may be even higher (Lindsay et al, 1991; La Pera et al, 2001; Rhoden et al, 2001; Schwarzer et al, 2001; Sommer et al, 2002; Mulhall et al, 2004b; El-Sakka, 2006; Arafa et al, 2007; DiBenedetti et al, 2011). Another misconception is that PD has a reasonable likelihood of resolving spontaneously. As a result, men are often told by their physicians that nothing can be done during the acute phase and they should wait 6 months to a year, because there is a "good chance" that the disease process will resolve. We now know from multiple natural history studies that

full spontaneous resolution is extremely rare and that it is more likely that within the first 12 to 18 months after presentation, if no treatment is offered, up to 50% of patients will experience worsening of their deformity (Mulhall et al, 2006). Another misconception is that PD is a disorder that occurs only in middle-aged men. Multiple studies have demonstrated that it can occur in teenagers to men in their late 70s (Levine and Dimitriou, 2000; Kadioglu et al, 2002; Tal et al, 2012). Why this process occurs more commonly in middle-aged men is unclear, but theories include that the aging tunica is more apt to be injured in men who are susceptible to the disease, which activates the abnormal wound-healing process (Devine and Horton, 1988; Jarow and Lowe, 1997).

It is also a disorder that appears to go through an active phase during which the scar can grow, resulting in progressive deformity and pain. However, once it stabilizes, there is rarely further progression (Box 31-1).

NATURAL HISTORY

An understanding of the natural history of PD is critical to counseling patients and selection of treatment options. There are two phases. The first is the active (acute) phase, which is commonly associated with painful erections and changing deformity of the penis. This is followed by a stable (chronic) phase, which is characterized by stabilization of the deformity and disappearance of painful erections (Devine et al, 1997; Jalkut et al, 2003; Ralph et al, 2010; Kadioglu et al, 2011a). It would seem intuitive that once the scarring process has begun, there would be a progressive increase in deformity; but we have found that up to 20% of patients will experience a sudden onset of deformity that can be as great as 90 degrees.

It has been reported that PD can completely resolve in some patients, but this is probably a misconception. It is more likely that some men who traumatize their penises develop curvature secondary to the local inflammatory process. In some of these patients the inflammation resolves before scarring sets in. Thus the patient who has resolution of his deformity may not have had PD at all, but rather a slow-healing wound that simply takes longer to undergo the proper remodeling found with normal wound healing. Spontaneous regression has been looked at in several contemporary natural history studies that have suggested that no more than 13% of patients will have some improvement of their deformity over the first 12 to 18 months after onset of the disease process

BOX 31-1 Peyronie Disease Caveats

- Peyronie disease is not rare.
- It does not have a high likelihood of spontaneous resolution.
- It is not a disease of only middle-aged men.
- It is not a disease of only Caucasian men.
- Trauma to the flaccid and erect penis appears to activate the scarring process in susceptible men.
- Erectile dysfunction is frequently found in men with Peyronie disease.
- Plaque calcification is not an indication of mature, chronic-phase disease.

when not treated (Kadioglu et al, 2002; O'Brien et al, 2004; Mulhall et al, 2006; Hatzimouratidis et al, 2012). The key point to remember is that complete spontaneous resolution of PD is a rare occurrence. Recently, Berookhim and associates (2014) reported on a group of men who elected to have no treatment of their PD. In this study it appeared that the later the man sought evaluation in the first year after the onset of symptoms, the less likely that he would experience further deformity when left untreated (Berookhim et al, 2014).

EPIDEMIOLOGY**Incidence**

The incidence of PD varies widely depending on the population being screened—from 0.39% to 20.3%, with most current estimates of the incidence of PD being between 3% and 9% and the peak age of onset of PD in the early 50s (Schwarzer et al, 2001; Mulhall et al, 2004a). It was previously held that this was a disorder primarily of Caucasian men of northern European descent. It is now recognized that men of every race can develop PD. The variation in recognition of and reporting on this disorder in certain populations may be a result of the interest and presence of physicians with expertise in PD, as well as cultural mores that may make it more or less comfortable for men to share information about changes in their sexual function with a health care provider (Lindsay et al, 1991; Arafa et al, 2007). A recent Japanese study looked at a total of 1090 men undergoing a routine health check and demonstrated the prevalence of PD in healthy men to be quite low at 0.6% (Shiraishi et al, 2012). In a large U.S. Web-based survey, 16,000 randomly selected men over the age of 18 years were asked to self-report the symptoms, diagnosis, or treatment of PD. In this study, 0.5% to 0.8% of respondents had received a diagnosis of or treatment for PD, whereas 13% of respondents admitted to having symptoms of PD such as penile deformity or palpable plaque (DiBenedetti et al, 2011). The estimated number of unknown cases seems to be much greater than the number of symptomatic patients seeking treatment because autopsy data demonstrate that 22 out of 100 men have at least a mild form of the disease (Smith, 1969). Therefore the prevalence of PD seems to be equivalent to if not greater than that of important public diseases such as diabetes and urolithiasis, both established to be present in 3% to 4% of the general population (Sommer et al, 2002). It is worthwhile to note that the actual rates of PD may be higher than self-reported studies would suggest, because men with PD may be reluctant to discuss the signs and symptoms of this embarrassing condition.

The incidence of symptomatic PD may be increasing, which is perhaps explained by an increasing tendency to obtain medical help, increasing awareness that may be secondary to people seeking information on the Internet, or increasing use of pharmacologic treatments for ED (e.g., phosphodiesterase inhibitors, intracavernosal injectable agents) (Hellstrom, 2003). Phosphodiesterase inhibitors have not been suggested to directly contribute

to the development of PD; rather, their associated use in those with medical conditions such as diabetes that contribute to ED is the likely explanation, because these men now experience erections with deformities they would not have realized were present. At this time there is no suggestion that use of phosphodiesterase type 5 (PDE5) inhibitors should worsen or provoke PD. On the other hand, more recent in vitro and animal model studies have suggested that use of PDE5 inhibitors, as nitric oxide (NO) donors, has an antifibrotic effect that may be beneficial for the patients with PD (Valente et al, 2003; Ferrini et al, 2006; Gonzalez-Cadavid and Rajfer, 2009; Chung et al, 2011a). Treatments for ED, including intracorporeal injection therapy and vacuum devices, have also been implicated as a cause of PD (Carrieri et al, 1998; Jalkut et al, 2003; Bjekic et al, 2006). What seems more likely is that these treatments are designed to create a stronger erection, which can then be injured during a sexual encounter, activating the disease process in the susceptible individual. To date there is no evidence that any medicines such as beta blockers or phenytoin cause PD.

Associated Conditions**Aging**

PD is most commonly diagnosed in the fifth decade of life. A linear increase in prevalence can be seen from ages 30 to 49 with an exponential increase in prevalence at age 50 and up (Sommer et al, 2002). Mulhall and associates (2004b) demonstrated an increased prevalence of 8.9% in a population being screened for prostate cancer in a study in which the mean patient age was 68 years (Mulhall et al, 2004b). PD may also occur in young men. PD patients under age 40 tend to be seen during the acute phase after rapid onset of disease with a penile deformity and pain on erection (Tefekli et al, 2001). Studies have shown that approximately 10% of men with PD are younger than 40 years (Levine and Dimitriou, 2000). In addition, Tal and associates (2012) reported on 32 teens diagnosed with PD over a 10-year period with a mean age of 18 (Tal et al, 2012). Sixteen percent reported antecedent trauma, and 37% reported subsequent ED. A high level of distress was reported by 94% of these young men, with 34% seeking treatment for an anxiety or mood disorder (Tal et al, 2012). The increased prevalence of PD with age is likely a reflection of the increased likelihood of comorbid medical conditions contributing to the development of ED such as hypertension, hyperlipidemia, diabetes, and low testosterone, all of which have been suggested as possible causative factors associated with PD. Hypothetically, it could also reflect the reduced tissue elasticity that naturally occurs with aging, predisposing this tissue to stretch-related injury.

Diabetes

One of the more interesting recently studied associations is that of diabetes mellitus and PD. The prevalence of diabetes in men with PD has been reported to be as high as 33.2%, which is much higher than in the general population (Kadioglu et al, 2002; Bjekic et al, 2006; Cowie et al, 2010). Conversely, the prevalence of PD among diabetics has been shown to be increased when compared with the general population, with a reported rate of 8.1% to 20.3% depending on the specific population being screened (El-Sakka and Tayeb, 2005; Tefekli et al, 2006; Arafa et al, 2007). This may reflect particular patient populations, ethnic groups, referral patterns, and expertise of the physicians treating the disorder. Longer duration of diabetes and poor glucose control have also been shown to significantly increase the severity of PD with respect to duration of PD, deformity, curvature, and erectile function (El-Sakka and Tayeb, 2005; Kendirci et al, 2007). A recent retrospective study suggested that plaque size and pain may decrease as underlying diabetes is treated (Cavallini and Paulis, 2013). This was a small retrospective study, and further prospective studies are necessary to confirm these results.

One theory for the apparent association between PD and diabetes is that men with diabetes are at a higher risk for ED, which may

Figure 31-1. Demonstration of the mechanism of injury during buckling injuries to the penis. **A**, Fibers of the septal strands dorsally fan out and are interwoven with the inner circular lamina fibers of the tunica albuginea. The outer lamina consists of longitudinal fibers. **B**, In the chronic mechanism of Peyronie disease, less turgid erections allow flexion of the penis during intercourse, producing elastic tissue fatigue, further reducing elasticity of the tissue and leading to multiple smaller ruptures of the fibers of the tunica with smaller collections of blood, possibly producing multiple scars. **C**, In the acute mechanism of Peyronie disease, bending the erect penis out of column produces tension on the strands of the septum, delaminating the layers of the tunica albuginea. Bleeding occurs, and the space fills with clot. The scar generated by the response of the tissue to this process becomes the Peyronie disease plaque. **D**, Illustration of the situation on the ventrum of the penis, where the bilaminar arrangement of the tunica albuginea becomes thinned, with the midline being monolaminar. The fibers of the septal strands fan out and are interwoven with the inner circular layer. There is no outer circular layer. **E**, In the chronic mechanism of Peyronie disease, less turgid erections allow buckling of the penis as in **B**. **F**, In the acute mechanism of Peyronie disease, buckling of the erect penis out of column produces tension on the strands of the septum, causing the septal fibers to tear.

predispose to injury during intercourse because of the less rigid penis pivoting back and forth, potentially resulting in a tissue fatigue-type fracture, activating the scarring disorder (Devine and Horton, 1988) (Fig. 31-1). Another theory suggests that diabetes may lead to decreased compliance of tissues as a result of increased collagen cross-linking (Aronson, 2003). This may make minor injuries less prone to normal remodeling.

Erectile Dysfunction

ED appears to be more common in men with PD than in the general population (Ralph et al, 2010). The prevalence of ED in men with PD has been reported to be 37% to 58% (Kadioglu et al, 2002; Usta et al, 2004; Casabé et al, 2011; Chung et al, 2011b). In a duplex ultrasound study of 76 men with PD and ED, 36% had evidence of penile arterial insufficiency and 59% had veno-occlusive disease as the cause of their ED (Lopez and Jarow, 1993). In our review of their own clinical experience, approximately 80% of men with PD also have reported diminished rigidity. Half of these men had ED before the onset of PD, usually as a result of the typical vascular risk factors for ED (e.g., smoking, diabetes, hypertension, dyslipidemia), whereas the other half developed ED subsequent to the onset of the PD. The prevalence of associated comorbidities is higher in patients with PD and ED than in patients with PD, which may indicate that hypertension, smoking,

hypercholesterolemia, diabetes mellitus, and hyperlipidemia are more likely related to ED than to the pathogenesis of PD (Usta et al, 2004). This later onset may be attributable to changes in penile geometry and/or psychological inhibition, which is difficult to determine even in studies in which duplex ultrasound and cavernosometry are used (Levine and Coogan, 1996; Kadioglu et al, 2002).

Psychological Aspects

PD is not only a physically deforming but also a psychologically devastating disorder. Multiple studies have now demonstrated the frequent association of psychological distress in men with PD including diminished self-esteem, shame, embarrassment, self-disgust, anxiety, loss of sexual confidence, and depression, all of which can compromise the man's relationships at home, at work, and in the bedroom (Gelbard et al, 1990; Jones, 1997; Rosen et al, 2008; Smith et al, 2008a). Penile shortening and the inability to have intercourse are the two most common and consistent risk factors for emotional distress and relationship problems associated with PD (Rosen et al, 2008; Smith et al, 2008a).

Psychosocial stress is reported by 77% to 94% of men with PD (Gelbard et al, 1990; Tal et al, 2012; Nelson and Mulhall, 2013). Contemporary studies using a validated measure of depression (Center for Epidemiologic Studies Depression Scale [CESD]) have

demonstrated moderate to severe depression in 48% of PD patients, and these rates typically increase with the duration of PD (Nelson et al, 2008). PD also commonly affects the patient's sexual partner, causing feelings of helplessness as well as feelings of personal responsibility for the PD caused by trauma during intercourse, and sadness over loss of intimacy (Rosen et al, 2008).

In an effort to develop a valid outcome measure for assessing psychosocial and sexual consequences of PD, Rosen and associates (2008) conducted a study composed of a series of focus groups with 28 PD patients and identified common concerns. These concerns were grouped into four core domains: (1) physical appearance and self-image, (2) sexual function and performance, (3) PD-related pain and discomfort, and (4) social stigmatization and isolation (Rosen et al, 2008). With these data, a validated Peyronie's Disease Questionnaire (PDQ) was developed; patient-reported estimates of penile curvature severity correlated with PDQ domains, whereas objective measures of penile curvature did not. Thus for some patients even a lesser degree of curvature may be highly bothersome or provoke distress (Hellstrom et al, 2013). This is also evidenced by the fact that self-estimates of penile curvature in men with PD differ from objective measures by an average of 20 degrees, with 54% of patients overestimating their curvature (Bacal et al, 2009). It is important to remember that despite "successful treatment" that may allow the patient to be sexually functional again, there is often persistent psychological distress, presumably because of the residual changes to the patient's pre-PD penis (Gelbard et al, 1990; Jones 1997). It is critical that the physician recognize these psychological effects, not only to enhance the trust between the patient and physician, but also to identify more advanced indicators of depression, which should initiate referral to a sex therapist, psychologist, or psychiatrist (Levine, 2013).

Radical Prostatectomy

Both prostate cancer and PD are most prevalent in men after their fifth decade of life. The evidence to support or refute a link between radical prostatectomy and PD is limited. In a study of 1011 post-radical prostatectomy patients, Tal and associates (2010) demonstrated an incidence of PD of 15.9% with a mean time to development of disease of 13.9 months (Tal et al, 2010). Although postoperative erectile function was not a predictor of development of PD, younger age at time of prostatectomy and white race were reported risk factors for developing PD after radical prostatectomy. The authors concluded that prospective controlled studies are needed to elucidate the incidence of PD after radical prostatectomy and determine if radical prostatectomy has a causative role in the pathogenesis of PD (Tal et al, 2010).

Ciancio and Kim (2000) also examined the effects of prostatectomy on penile fibrosis and sexual dysfunction. Eleven percent of all patients undergoing prostatectomy developed fibrotic changes in the penis. This fibrosis led to penile curvature in 93%, "waist-band" deformity in 24%, and palpable plaques in 69%. Therefore, it does appear that men undergoing radical prostatectomy by an open or robotic approach have a higher risk of developing PD than the general population. The mechanism responsible for this is not known but may include perioperative penile trauma, neurogenic consequences, or as we believe is local release of cytokines that activate the abnormal wound-healing process in men susceptible to PD.

Hypogonadism

The possibility that low serum testosterone may be associated with PD has also been investigated. Results of studies have varied on this topic. Moreno and Morgentaler (2009) demonstrated that severity of curvature was worse in men with low free and total testosterone. Rhoden and associates could demonstrate no such association and concluded in their study that androgen serum levels and sexual dysfunction had no association to PD (Rhoden et al, 2010).

The presence of hypogonadism in patients with PD has been suggested to exaggerate the severity of PD. Nam and associates (2011) showed in a study of 106 patients with PD that curvature, plaque size, ED, and response to medical therapy were worse in patients with testosterone deficiency and concluded that further studies are needed to confirm this relationship. Cavallini and associates (2012) investigated whether testosterone replacement in hypogonadal men with PD would affect treatment with intraleisional verapamil injection. In these patients, supplementation with testosterone improved the efficacy of intraleisional verapamil compared with those who did not receive testosterone replacement. Plaque area and penile curvature were also more severe in hypogonadal men with PD (Cavallini et al, 2012).

Collagen Disorders

There does appear to be an association of PD with other collagen disorders such as Dupuytren disease (DD). DD is believed to be transmitted in an autosomal dominant manner. The prevalence of DD in different geographic locations is extremely variable (0.2% to 56%), and it is not clear whether this is because of genetic or environmental factors. The literature concerning coexisting DD in patients with PD also demonstrates a very large range (0.01% to 58.8%) (Nugteren et al, 2011). As with PD, the prevalence of DD increases with age, from 7.2% among men in the age group of 45 to 49 years up to 39.5% in those 70 to 74 years old (Gudmundsson et al, 2000). Other studies have demonstrated DD in 21% to 22.1% of PD patients, as well as 6.7% who reported having a first-degree relative with DD (Carrieri et al, 1998; Nugteren et al, 2011). Other associated fibrotic conditions are contracture of the plantar fascia (Ledderhose disease) and tympanosclerosis, both of which are uncommon disorders (Box 31-2).

KEY POINTS: EPIDEMIOLOGY

- The incidence of PD varies widely depending on the population being screened and is likely much higher than once thought. Current estimates are between 3% and 9%, and the peak age of onset of PD is the early 50s.
- A linear increase in prevalence can be seen from ages 30 to 49, with an exponential increase in prevalence at age 50.
- PDE5 inhibitors have not been suggested to directly contribute to the development of PD; rather, their associated use in those with medical conditions that contribute to ED likely unmasks deformities that would have otherwise gone unrecognized.
- The prevalence of PD among diabetics has been shown to be 8.1% to 20.3% depending on the population screened, which is higher than in the general population. This may reflect particular patient populations, ethnic groups, referral patterns, and expertise of the physicians treating the disorder.
- The prevalence of ED in men with PD has been reported to be 37% to 58%.
- PD is not only a physically deforming but also a psychologically devastating disorder, with 48% of patients showing signs of moderate to severe depression; in general, these rates increase with the duration of PD. Penile shortening and inability to have intercourse are the two most common and consistent risk factors for emotional and relationship problems associated with PD.
- There appears to be an increased incidence of PD in men who have undergone radical prostatectomy, although further prospective studies are required to confirm this association.
- Although hypogonadism may be associated with PD, there is no clear evidence that it is a risk factor. Further study is indicated, and assessment of serum testosterone is recommended.

Figure 31-2. The outer layer bundles, which are coarser and directed in a longitudinal manner, often form an incomplete layer (regions 4 to 5 o'clock, 7 to 8 o'clock, and 11 to 1 o'clock) and condense to form ligament-like structures. Artist's drawing of penis depicts dorsal and ventral thickening and pillars. (Data from Brock G, Hsu GL, Nunes L, et al. The anatomy of the tunica albuginea in the normal penis and Peyronie's disease. *J Urol* 1997;157:276–81.)

PENILE ANATOMY AND PEYRONIE DISEASE

The exact cause of PD remains to be determined. Ongoing studies continue to clarify this disorder on the genetic, molecular, and anatomic level. The corpora cavernosa, the erectile bodies of the penis, surrounded by the tunica albuginea possess the ability to become rigid by becoming engorged with blood. The tunica albuginea is a multilayered structure predominantly composed of type 1 collagen that is oriented with an inner circular and outer longitudinal layer interlaced with elastin fibers separated by an incomplete septum (Gentile et al, 1996; Brock et al, 1997; Kelly, 2007). This septum is anchored into the inner circular layer and is key to the structural integrity of the tunica; without it, computer models have demonstrated that the stress generated by a full erection of one contiguous corporeal body would be sufficient to rupture the tunica albuginea (Mohamed et al, 2010). These anchor sites are susceptible to microvascular trauma and tunical delamination, which may be one of the triggers leading to this disease (Devine et al, 1997). The structure is further reinforced by intracavernous pillars, which anchor the tunica albuginea across the corpora cavernosa at the 2 to 6 o'clock and 10 to 6 o'clock positions, with finer pillars at the 5 and 7 o'clock positions (Fig. 31-2) (Brock et al, 1997). It is

Figure 31-3. Photomicrographs of the tunica albuginea. A, Normal tunica albuginea demonstrating the polarized arrangement of collagen. B, Peyronie plaque demonstrating the nonpolarized arrangement of collagen and the haphazard arrangement of elastin. Collagen stains green; elastin stains black.

interesting to note that 60% to 70% of plaques are located on the dorsal aspect of the penis and are usually associated with the septum (Pryor and Ralph, 2002). It is possible that pressures on the penis during intercourse may cause a delamination between the two layers, activating the abnormal wound-healing process, which is trapped within the tunic, fostering the progressive scarring.

The longitudinal layer of the tunica albuginea is thinnest at the 3 and 9 o'clock positions of the corpora; it is completely absent between the 5 and 7 o'clock positions (Brock et al, 1997). This may contribute to greater ease of dorsal buckling and may explain why most PD patients exhibit dorsal curvature (Devine and Horton, 1988; Border and Ruoslahti, 1992; Brock et al, 1997; Devine et al, 1997; Jarow and Lowe, 1997). In normal tunical tissue, each layer appears to be distinct and is able to slide on the adjacent layer. The normal three-dimensional structure of the tunica affords great flexibility, rigidity, and tissue strength to the penis despite the fact that the tunica albuginea is quite thin—1.5 to 3.0 mm, depending on the position around the circumference. Normal architecture is essentially lost consequent to this disease, resulting in what is known as a Peyronie “plaque,” which when examined histologically demonstrates disorganization of collagen fibrils as well as a decrease in and disorganization of elastin resulting in penile deformity caused by asymmetrical expansion of the corpora (Figs. 31-3 and 31-4) (Akkus et al, 1997; Brock et al, 1997; Devine et al, 1997; Costa et al, 2009). When expansion is limited at one point along the circumference of the corpora by the inelastic scar of the Peyronie plaque, deviation to that side occurs; a circumferential plaque may lead to an hourglass deformity (Akkus et al, 1997; Devine et al, 1997).

Inflammatory mechanisms and oxidative stress in Peyronie's disease: therapeutic "rationale" and related emerging treatment strategies. *Inflamm Allergy Drug Targets* 2012;11:48–57.)

Impact of Wound Healing on the Development of Peyronie Disease

In general, PD has been described as a wound-healing disorder of the tunica albuginea. Recent investigations have focused on the mechanisms of wound healing, fibrosis, and scar formation and have correlated the findings with the PD population. Normal wound healing involves three phases: an acute phase, a proliferative phase, and a remodeling phase. These are not to be confused with the acute and chronic phases of PD previously described. By understanding the wound-healing process, one gains a better understanding of PD, targets for drugs used to treat PD, and the animal models that have been developed for the study of PD. In general, during the **acute phase**, blood vessel injury leads to extravasation of blood and aggregation and activation of platelets that release chemotactic agents that act as promoters in the wound-healing cascade by activating and attracting neutrophils during the first 24 hours after clot formation, macrophages after 48 hours, and finally lymphocytes after 72 hours (DiPietro, 1995). Macrophages phagocytose dead or potentially injurious material and destroy bacteria or other foreign cells via oxygen free radical reactions. In addition, macrophages activate keratinocytes, fibroblasts, and endothelial cells by releasing potent tissue growth factors, particularly transforming growth

factor-β (TGF-β), as well as other mediators such as TGF-α, heparin binding epidermal growth factor, fibroblast growth factor (FGF), and collagenase (DiPietro, 1995; Ravanti and Kahari, 2000).

The next phase of normal wound healing is the **proliferative phase**, which marks the shift toward tissue repair beginning at approximately 72 hours after injury and persisting for approximately 2 weeks. It is characterized by fibroblast and myofibroblast migration in response to TGF-β and platelet-derived growth factor (PDGF), as well as deposition of newly synthesized extracellular matrix (ECM) composed of type I and type III collagen, hyaluronan, fibronectin, and proteoglycans (Velnar et al, 2009). At this point, fibroblasts are stimulated by TGF-β to change into myofibroblasts, which contain thick actin bundles allowing for wound contraction. TGF-β also signals fibroblasts and myofibroblasts to synthesize types I and III collagen (Tomasek et al, 2002; Gelbard, 2008).

Finally, the **remodeling phase** begins and in the normal situation may last up to 1 or 2 years. The remodeling of an acute wound is tightly regulated by mechanisms that balance the simultaneous degradation and synthesis of collagen as well as other ECM macromolecules. Any alterations in this process may lead to abnormal wound healing with excessive scarring (Velnar et al, 2009). Matrix metalloproteinases (MMPs) (collagenases), produced by neutrophils, macrophages, and fibroblasts in the wound, are responsible for the degradation of collagen. They are subsequently

held in check by inhibitory factors called tissue inhibitors of metalloproteinases (TIMPs). As the activity of TIMPs increases, there is a drop in matrix breakdown by metalloproteinase enzymes, thereby promoting new matrix accumulation (Ravanti and Kahari, 2000). This balance between TIMPs and MMPs has also been studied in the pathogenesis of PD and is described later in this section.

Over time the highly disorganized initial deposition of collagen matrix becomes more oriented and cross-linked during the final stages of the remodeling phase. The process is regulated by a number of factors, with PDGF, TGF- β , and FGF being the most important (Velnar et al, 2009), but also including MMPs, TIMPs, fibrin or plasminogen activator inhibitor-1 (PAI-1) (Taylor and Levine, 2007; Velnar et al, 2009). Having accomplished this task, redundant fibroblasts and myofibroblasts are eliminated by apoptosis. A fundamental understanding of the elements of normal wound healing provides a foundation for understanding which components may go awry in PD. It does appear that most basic science research in this field has focused on the development of the scarring process resulting in the exuberant scar found in men with PD. More recent research has focused on the dysregulation of remodeling that may be responsible for why the fibrosis does not resolve.

ETIOLOGY OF PEYRONIE DISEASE

The exact cause of PD has not yet been defined, although most would agree that some injurious stimulus is necessary to trigger the cascade of events that leads to PD in the susceptible individual (Devine et al, 1997; Jarow and Lowe, 1997; Carrieri et al, 1998; Jalkut et al, 2003; Bjekic et al, 2006; Nachtsheim and Rearden, 1996). Trauma may be perceived as a single event experienced by the patient or may take the form of repetitive microtrauma to the penis. Furey (1957) initially suggested that trauma was the primary cause of PD (Furey, 1957).

The proposed mechanism is that in the erect state, the pressures inside the penis can get quite high and acutely higher when external forces are placed on the penis during intercourse in particular. These pressures may exceed the elasticity and strength of the tunica tissues, resulting in a microfracture. A commonly held misconception is that the trauma to the penis must occur only when it is erect; however, in our experience we have noted that trauma to the flaccid penis may also trigger this process. In a recent review of our database of 228 patients who had recognized trauma to the penis shortly before the onset of PD, 16% reported a traumatic event to the flaccid penis (e.g., motor vehicle accident, sports-related injury). As the scar develops, there may also be an inflammatory response, resulting in the pain that can be present in the flaccid penis or when pressure is placed on the penis. Dorsal and ventral shear stresses occurring during sexual activity may account for the more common dorsal location of plaques (Devine et al, 1997). Investigators have suggested that repetitive microtrauma to the penis leads to delamination of the tunica albuginea and vessels between the layers of the tunica (Somers and Dawson, 1997). This leads to microhemorrhage and initiates the wound-healing cascade described previously.

Carrieri and associates (1998) reported a 16-fold increase in PD in those who had undergone prior invasive procedures as well as a nearly 3-fold increase in PD in patients who had experienced genital and/or perineal trauma (Carrieri et al, 1998). It is also important to note that although trauma has been considered the most likely trigger activating PD, in our clinical experience no more than 30% of men recall a specific event involving injury to the penis close to the time when the scarring or pain began. Other investigators have reported 16% to 40% of patients having had antecedent trauma (Bjekic et al, 2006; Tal et al, 2012). An injury occurring during sexual activity appears to be the most common recognized event associated with the onset of PD. An association with trauma and position of intercourse has been proposed for some time, based on the assumption that certain positions may be more apt to cause injury. This has not been verified but it does appear from anecdotal experience that the most common sexual

position noted to precede the onset of PD is with the partner on top. In this position, a sudden “faux pas de coit” or missed thrust may lead to high intracorporeal pressures (Bitker et al, 1988).

Although trauma undoubtedly plays a pivotal role in the development of disease, it alone cannot explain why some men develop deformity whereas others do not. This is no better illustrated than by a study of 193 penile fracture patients in whom none went on to develop PD (Zargooshi, 2004). Several underlying factors have been considered responsible for PD; genetic predisposition, autoimmune factors, an aberration of localized wound healing, and even infection have been proposed as possible causes (Devine et al, 1991; Ralph et al, 1996; Mulhall et al, 2002; Jalkut et al, 2003; Taylor and Levine, 2007). Therefore, we should be careful about the medicolegal implications of referring to PD as the result of treatments for ED, trauma to the flaccid penis, or catheterization or endoscopy, which are more likely just providing an opportunity for the forces at hand to activate the abnormal wound-healing response in the “genetically” susceptible man rather than being the cause of PD (Carrieri et al, 1998; Levine and Latchamsetty, 2002). The following discussion focuses on specific research into the pathophysiology of PD.

Role of Oxygen Free Radicals and Oxidative Stress

Oxidative stress has a well-documented role in tissue fibrosis and has been studied in the pathogenesis of PD (Gonzalez-Cadavid and Rafjer, 2005). As stated previously, microvascular trauma leads to extravasation of blood, with thrombus formation that leads to deposition of fibronectin and fibrin. Inflammation ensues with accumulation of inflammatory cells and production of reactive oxygen species (ROSs). During the early phase of PD an increase in oxidative stress in the form of free radicals induces overexpression of fibrogenic cytokines and augmented transcription and synthesis of collagen. ROSs are increased by TGF- β 1, which also directly inhibits collagenase and promotes collagen synthesis (Magee et al, 2002). ROSs include superoxide anion, hydrogen peroxide, hydroxyl radical, organic hydroperoxide, alkoxy radicals, and peroxy radicals. Although NO seems to play an antifibrotic role, nitrosative stress as well as oxidative stress can lead to macromolecular damage, cytotoxic effects, lipid peroxidation, DNA fragmentation, collagen accumulation, and cellular dysfunction (Paulis and Brancato, 2012).

Role of Nitric Oxide in Peyronie Disease

NO is a small reactive free radical that acts as both an intracellular and an extracellular regulatory molecule. Wound cells, including monocytes, macrophages, and fibroblasts, have been shown to synthesize NO through a nuclear factor- κ B (NF- κ B)-activated inducible NO synthase (iNOS)-dependent mechanism after injury. The iNOS isoform produces NO; it is usually considered a defense mechanism against infection or cancer, is associated with inflammation, and is significantly increased in human and animal PD plaques (Gonzalez-Cadavid, 2009). NO synthesized by iNOS reacts with ROSs, thus reducing ROS levels and presumably inhibiting fibrosis. The antifibrotic effects of NO may be mediated at least in part by the reduction of myofibroblast abundance and may lead to a reduction in collagen I synthesis (Vernet et al, 2005). NO may also play an antifibrotic role by activating guanylyl cyclase, thus producing cyclic guanosine monophosphate (cGMP), which has been suggested to inhibit plaque formation (Ferrini et al, 2002; Valente et al, 2003).

Role of Myofibroblasts in Peyronie Disease

The excessive deposition of collagen and ECM accompanied by the loss of functional cells that characterizes tissue fibrosis is caused in some cases by the appearance and accumulation of myofibroblasts (Gonzalez-Cadavid, 2009). Twenty percent of cells cultured from PD tunica albuginea are in fact myofibroblasts, suggesting that they may be one of the primary factors leading to fibrosis in PD (Mulhall

et al, 2002). Proposed mechanisms for the presence and persistence of myofibroblasts include a decrease in myofibroblast apoptosis, as well as stimulation of fibroblast transformation to myofibroblasts by TGF- β and mechanical stress, which has been associated with hypertrophic scarring (Darby and Hewitson, 2007; Gelbard, 2008). Myofibroblast activation is a key event in the development of fibrosis. Trauma to the tunica albuginea secondary to microscopic delamination increases the adherence of fibroblasts to their surroundings, exposing them to changes in ECM tension, and in the presence of appropriate cytokines initiates their differentiation into myofibroblasts (Gelbard, 2008). When tension diminishes, myofibroblasts tend to undergo apoptosis. Gelbard postulated that if myofibroblasts are continuously exposed to tension in the form of rigid corpora during erections, they may fail to undergo apoptosis and subsequently contribute to what appears to be a hallmark of PD—inappropriate and persistent stimulation of the wound-healing process (Gelbard, 2008).

Role of Transforming Growth Factor- β 1 in the Etiology of Peyronie Disease

TGF- β 1 has been shown to be significantly associated with PD (El-Sakka et al, 1997). TGF- β is a strong activator of myofibroblasts and is known to be a potent fibrotic growth factor by stimulating the deposition of ECM. TGF- β binds cell surface receptors and through a signal transduction cascade leads to the deposition and remodeling of ECM by stimulating cells to simultaneously (1) increase the synthesis of most matrix proteins (Ihn, 2002); (2) decrease production of matrix-degrading proteases while increasing the production of inhibitors of these proteases (Knittel et al, 1999); and (3) modulate the expression of integrins (Margadant and Sonnenberg, 2010). The action of TGF- β in tissue repair has been shown to involve an initiation of complex sequences of monocyte chemoattraction, induction of angiogenesis, and control of the production of cytokines and other inflammatory mediators (Border and Ruoslahti, 1992). Moreover, TGF- β stimulates the synthesis of individual matrix components including fibronectin, tenascin, collagens, and proteoglycans, while simultaneously blocking matrix degradation by decreasing the synthesis of proteases and increasing levels of protease inhibitors (Balza et al, 1988). All these events can be beneficial in tissue repair; however, the deposition of ECM at a site of tissue injury can lead to scarring and fibrosis. Furthermore, the ability of TGF- β to induce its own production may be the key to the development of scarring and fibrosis (Border and Ruoslahti, 1992). TGF- β 1 is not the only member of the large TGF- β superfamily of growth and differentiation factors (GDFs) that have been implicated as fibrotic agents. Myostatin, also known as GDF-8, has been proposed not only as an inhibitor of myofiber formation but also as an inducer of fibrosis. Myostatin is expressed in the normal human tunica albuginea (TA) and overexpressed in PD plaque. Myostatin stimulates myofibroblast generation and collagen deposition in normal tunic and is upregulated by TGF- β 1. Myostatin seems to potentiate the effects of TGF- β 1 (Cantini et al, 2008).

Fibrotic Gene Expression in Peyronie Disease

A variety of profibrotic and antifibrotic factors contribute to the development of PD plaque that leads to deformity (Grazziotin et al, 2004). Qian and colleagues performed DNA microarray analysis of PD tissue obtained from patients undergoing surgery for PD. The most highly upregulated gene found in the PD plaque, *PTN* or *OSF1*, codes for a secreted heparin-binding protein thought to stimulate mitogenic growth of fibroblasts and osteoblast recruitment, and is possibly related to plaque ossification. Proteins responsible for cell proliferation, cell cycling, and apoptosis were found to be increased, whereas Id-2, an inhibitor of myofibroblast differentiation, was downregulated. The second most upregulated gene, *MCP-1*, is critical to the inflammatory response and ossification (Graves, 1999; Graves et al, 1999). Genes related to myogenic

conversion during wound healing and fibroblast differentiation into myofibroblasts were upregulated, whereas collagenase IV, which is critical for collagen degradation and is decreased in fibrosis, was downregulated (Magee et al, 2002). Qian and associates (2004) performed a study comparing gene expression profiles of PD patients with those of DD patients. A series of 15 genes were upregulated and none were downregulated in the PD plaque versus the normal TA. Of the genes upregulated, the ones most prominently increased were MMPs involved in collagen breakdown, specifically MMP-2 or MMP-9 in one half of the PD plaques, in addition to genes involved in actin-cytoskeleton interactions required for fibroblasts and myofibroblasts to generate the contractile forces (Qian et al, 2004). According to the findings of another study, the lower expression of apoptotic genes may cause the persistence of collagen-producing cells that are upregulated, consequently resulting in plaque formation. Similar expression levels of apoptotic genes in both tunica albuginea and Peyronie plaques may be caused by the generalized physiopathologic alterations in the tunica albuginea that lead to plaque formation at a vulnerable region subjected to recurrent trauma (Zorba et al, 2012).

Del Carlo and colleagues (2008) investigated the role of MMPs and TIMPs in the pathogenesis of PD by using harvested plaque from patients who had PD. PD tissue samples were found to have diminished or absent levels of MMP-1, MMP-8, and MMP-13 compared with matched perilesional tunica and non-PD controls. PD fibroblasts were cultured with soluble MMPs and TIMPs after treatment with TGF- β or interleukin-1 β (IL-1 β). They found that IL-1 β stimulation increased the production of MMP-1, MMP-2, MMP-8, MMP-9, MMP-10, and MMP-13 in PD fibroblasts, whereas TGF- β increased the production of only MMP-10 and decreased the production of MMP-13, suggesting that PD fibroblasts can be induced to make MMPs (Del Carlo et al, 2008). Baseline aberrant expression of p53, a cell cycle-regulating protein, has been demonstrated in PD fibroblasts as well as an absent response to sublethal DNA damage. This suggests a role for an aberration in the p53 pathway in the pathogenesis of this condition (Mulhall et al, 2001a).

When all this information is taken together, it is not hard to understand why there are myriad clinical presentations and treatments for this very complex disease. A variety of alterations may be present in a given patient, which may manifest as fibrosis with penile deformity (see Box 31-2). This has been demonstrated by Qian and colleagues, who found marked heterogeneity in gene expression profiles among men with PD (Qian et al, 2004). As suggested by the ensuing section on medical therapy, different medical treatments that target different disease mechanisms may not work uniformly among the PD population (see Fig. 31-4).

KEY POINTS: ANATOMY AND ETIOLOGY

- The longitudinal layer of the tunica albuginea is thinnest at the 3 and 9 o'clock positions of the corpora; it is completely absent between the 5 and 7 o'clock positions. This absence of the longitudinal layer ventrally may contribute to greater ease of dorsal buckling and may explain why most PD patients exhibit dorsal curvature.
- Normal architecture is essentially lost consequent to this disease, resulting in what is known as a Peyronie plaque, which when examined histologically demonstrates disorganization of collagen fibrils as well as a decrease and disorganization of elastin, resulting in penile deformity caused by asymmetric expansion of the corpora.
- Antecedent trauma has been reported in 16% to 40%; most would agree that some injurious stimulus is necessary to trigger a cascade of events that lead to PD in the susceptible individual.
- Oxygen free radicals, oxidative stress, NO, myofibroblasts, TGF- β 1, and fibrotic gene expression all play a key role in the development of PD and are key avenues for future research to further elucidate the exact mechanism behind the development of PD.

SYMPTOMS

The most frequent presenting symptoms of patients with PD include penile pain, erect deformity, and palpable plaque, as well as ED (Pryor and Ralph, 2002; Smith et al, 2008b; Chung et al, 2011a). Many men who have PD visit the doctor with a self-misdiagnosis of ED. Not all patients experience pain or are able to palpate a plaque, but the shortening, hinge effect, distal softening, and curvature, when present, are readily recognized. Pain, when present in the acute phase, can occur in the flaccid condition with palpation of the plaque, with erection, or during intercourse. Once the disease process is stable, most pain will resolve, but in some men the pain persists with what has been referred to as “torque” pain associated with a pulling sensation on the plaque when a strong erection occurs (Levine and Larsen, 2013). This should not be confused with the inflammatory pain of the acute phase.

Although curvature can be one of the most recognized and distressing deformities associated with PD, many men are capable of sexual activity with curvature up to 60 degrees, particularly if the curvature is dorsal and more gradual along the shaft. Men with ventral or lateral curvatures may have a more difficult time with intromission because of discomfort. Yet, it is not uncommon to hear that the partner does not complain of discomfort during coitus, regardless of the degree or direction of curvature. Patient estimates of curvature are unreliable. One study demonstrated that 50% of patients overestimated their degree of curvature by an average of 20 degrees (Bacal et al, 2009). Classification by degree of curvature was introduced by Kelami (1983). One center reported on the distribution of curvature by the Kelami classification and found that 39.5% of patients had 30 degrees (mild) or less, 35% had 31 to 60 degrees (moderate), and 13.5% had more than 60 degrees of curvature (severe); 12% had no curvature but did experience an hourglass deformity resulting in an unstable erection (Kadioglu et al, 2011b).

The PD plaque can manifest in a variety of configurations including cords; simple nodules; coinlike, irregular dumbbell shapes; or I-beam plaques. It appears that virtually all plaques have a septal component, which supports the concept of delamination of tunical fibers as a result of axial forces on the septum (Jordan, 2007). Pure septal plaques have also been reported and may result in narrowing, shortening, or no recognized deformity at all (Bella et al, 2007).

The orientation of the plaque usually defines the deformity. Therefore patients with a simple dorsal plaque are most apt to have dorsal curvature; but if there is transverse or spiraling scarring, which can be partial or circumferential, this could result in varying degrees of indentation including an hourglass deformity, which can result in an unstable penis, or a hinge effect as a result of the inability to tolerate axial forces in the erect condition (Pryor and Ralph, 2002). The distal softening of the shaft beyond the plaque is also difficult to understand, because dynamic infusion cavernosometry and cavernosography (DICC) studies have found that the pressures within the corpora cavernosa are equal, when measured, proximal and distal to the plaque (Jordan and Angermeier, 1993). The cause of distal flaccidity remains speculative and includes local cavernosal fibrosis extending from the involved tunic (Ralph et al, 1992) and site-specific venous leak.

EVALUATION OF THE PATIENT

As with all medical conditions, a detailed history is a critical part of the evaluation of the man with PD (Levine and Greenfield, 2003). The intake interview should focus on presenting signs and symptoms such as pain, deformity, and palpable plaque. The assessment should also include whether onset was gradual or sudden and the estimated time that symptoms began; it should be determined whether there was any inciting event that may have triggered the process, including direct external penile trauma to the

Figure 31-5. This patient had physical evidence of Dupuytren, Ledderhose, and Peyronie diseases.

flaccid or erect penis or instrumentation. The patient should be asked whether there is any personal or family history of other fibrotic disorders including DD and Ledderhose disease (Fig. 31-5). Patients should be carefully queried as to their erectile capacity, but ultimately the question is whether the patient is capable of intromission or incapable because of deformity and/or diminished rigidity. A useful question that has been shown to be an effective predictor of postoperative erectile function is “If your penis was straight with the same quality of rigidity that you have now, do you think it would be adequate for penetrative sexual activity?” (Levine and Greenfield, 2003; Taylor et al, 2012). Clearly if the patient does not feel his erections would be satisfactory with or without pharmacotherapy, this can help direct the patient to treatment with a penile prosthesis and straightening maneuvers; nonsurgical or other surgical approaches could result in improvement of deformity, but if there is persistent ED, such treatment would likely not give the patient a sexually functional erection.

Further information to be obtained from the sexual history will be whether there are any vascular risk factors for ED, including a history of diabetes, hypertension, elevated cholesterol, and smoking. This is also a useful time to determine if there are issues with premature or delayed ejaculation. A list of medications may also indicate underlying medical conditions that may predispose to ED.

The recently validated PD questionnaire (PDQ) (Rosen, 2008; Hellstrom et al, 2013) addresses not only the concerns of the patient regarding structural changes of the penis but also how PD affects his overall psychological condition. The current questionnaire has 15 questions assessing three domains, including (1) Peyronie psychological and physical symptoms (six items), (2) penile pain (three items), and (3) the effects of PD symptoms (six items). Each domain is intended to be an independent measure, and the scores are not summed for a total instrument score. Higher scores indicate a greater negative impact. With further experience, it may prove to be a useful assessment tool for patients making treatment decisions. The PDQ can be downloaded at www.auxilium.com/PDQ.

The value of a photograph taken at home of the erect penis has been controversial because of the inability to adequately represent and measure a three-dimensional deformity (Ohebshalom et al, 2007; Bacal et al, 2009). At the current time, with the prevalence of smartphones, a photograph can be taken by the patient from above and from the side in the erect state, which can

be useful during the initial consultation to get a general impression of the direction and severity of the deformity.

The physical examination should include a general assessment of the femoral pulses, appearance of the flaccid penis, and whether it is circumcised. To assess the Peyronie plaque, the penis should be examined on stretch, which allows easier identification of the plaque (Fig. 31-6). The location of the plaque may be useful to

Figure 31-6. Palpation of penis on stretch facilitates identification of plaque.

record, but measurement of the size of the plaque with any modality has been found to be inaccurate because the plaque is rarely a discrete lesion (Bacal et al, 2009; Ralph et al, 2010; Hatzimouratidis et al, 2012; Levine and Burnett, 2013). It has irregular borders and often extends into a septal cord (Levine and Greenfield, 2003; Ralph et al, 2010). Furthermore, there is no evidence that a reduction in plaque size as a result of treatment is at all associated with improvement of deformity (Levine and Burnett, 2013). The stretched penile length (SPL) is also a critical parameter to measure at the initial consultation. This is performed by placing the penis on stretch by grasping the glans and pulling at a 90-degree angle away from the body (Wessells et al, 1996). It is our preference to measure from the pubis to the corona dorsally, as these are two fixed points and facilitate repeated measurement during the course of treatment and follow-up. The consistency of the plaque may be recorded. A “rock hard” plaque may be an indicator of calcification but will need to be confirmed with some form of imaging, preferably ultrasonography (Fig. 31-7). A calcified plaque is readily identified on ultrasonography because of the hyperdensity of the plaque with shadowing behind it. Computed tomography and magnetic resonance imaging have little value in the evaluation of the man with PD, but further investigation is ongoing to determine whether these modalities can provide prognostic information (Andresen et al, 1998; Hauck et al, 2003).

Only recently has it been recognized that calcification may occur early after the onset of the scarring process, and therefore the previously held notion that calcification is an indication of chronic, severe, and/or mature disease appears untrue (Levine et al, 2013). Calcification is most likely the result of a different genetic subtype of PD in which there is activation of genes involved in osteoblastic activity (Vernet et al, 2005). Why some plaques undergo mineralization and others do not remains unknown, but it does appear that the extent of mineralization may have a bearing on a successful response to nonsurgical therapy; men with more extensive calcification are less likely to benefit from nonsurgical treatment (Chung et al, 2011a). Several investigators have indicated that intralesional injection therapy with verapamil and interferon (IFN) is less likely to be successful in men with significant calcification (Levine et al, 2002; Hellstrom et al, 2006). This is because the drug will not be able to get into or effect change within this

Figure 31-7. This ultrasound image demonstrates areas of dorsal and ventral calcification. Note shadowing behind calcified plaques.

mineralized tissue. Furthermore, investigators have also suggested that patients with extensive calcification are more apt to proceed to placement of a penile prosthesis (Breyer et al, 2007; Chung et al, 2012b). Recently a calcification grading system was published. The investigators found that patients with grade 3, or the most extensive, calcification (>1.5 cm in any dimension or multiple plaques ≥ 1.0 cm) were more likely to undergo surgery when they also had satisfactory erectile function. This is in contradistinction to those who had less severe calcification of grade 1 (<0.3 mm) or grade 2 (0.3 to 1.5 cm) or no calcification in whom there was no evidence of an increased likelihood of proceeding to surgery (Levine et al, 2013).

The role of vascular testing has not been clearly defined. In centers that see many men with this disorder, duplex ultrasound analysis is routinely performed as part of the initial evaluation, especially for those who are considered surgical candidates (Ralph et al, 2010; Hatzimouratidis et al, 2012; Levine and Burnett, 2013). Assessment of penile deformity in the erect state is critical to the evaluation. This has been shown to be most accurately measured after an office vasoactive injection as compared with a home photograph or vacuum-induced erection (Ohebshalom et al, 2007). The benefits of a complete duplex ultrasound assessment include identification of calcification during initial surveillance in the flaccid state, assessment of penile vascular flow parameters after intracavernosal injection of vasoactive agent, observation of the erectile response to the vasoactive injection compared with the patient's sexually induced erection at home, and provision of the best opportunity to objectively assess deformity (Figs. 31-8

and 31-9; Box 31-3). These parameters are absolutely critical to the decision process for the patient who is considering surgery (Fig. 31-10).

Several studies have demonstrated that preoperative erectile function correlates strongly with postoperative results (Jordan and Angermier, 1993; Levine and Greenfield, 2003; Taylor et al, 2012). In an analysis of the relationship of penile deformity to the vascular status of PD, patients with ventral curvature were most likely to have cavernous veno-occlusive dysfunction, which further confirms the concern about postoperative ED after grafting of ventral curves (Lowsley and Boyce, 1950; Kendirci et al, 2005).

Some authors have reported the use of DICC as a tool to assess penile vascular integrity and in particular venous leakage before surgery (Jordan, 2007; Alphs et al, 2010). This test appears to add unnecessary invasiveness and expense and provides little value to the diagnostic evaluation over a well-done dynamic penile duplex ultrasonography. Although no standard evaluation for assessment of penile sexual sensitivity has been established, light touch and biothesiometry can be used (Levine and Burnett, 2013). Biothesiometry has been suggested to be an indirect measure of penile sexual sensation. This is controversial because no definitive controlled studies have been reported (Padma-Nathan, 1988). The assumption is that the vibratory nerves travel with the unique sexual nerves of the penis. Therefore, vibratory appreciation with the index fingers used as the positive control and anterior thighs as the negative control can be a surrogate assessment of sexual sensation, which may be compromised by scar infiltration into the sensory nerves or because of other underlying systemic disorders such as diabetes mellitus. In response to the proposed increased prevalence of hypogonadism with PD, we recommend obtaining a morning serum total testosterone level during the initial evaluation (Moreno and Morgentaler, 2009).

Figure 31-8. Measurement of curvature with goniometer.

BOX 31-3 Value of Penile Duplex Ultrasonography for Peyronie Disease

- Identification and measurement of plaque calcification
- Identification of corporeal fibrosis
- Observation of erectile response to vasoactive intracavernosal injection
- Measurement of penile vascular parameters (peak systolic velocity, end-diastolic velocity, and resistive index)
- Optimum objective measurement of erect penile deformity (curvature, girth irregularities, hinge effect)

Figure 31-9. Instability or a hinge effect of the erect penis caused by indentation is demonstrated in this severely dorsally bent penis with application of axial pressure.

KEY POINTS: EVALUATION

- Detailed history includes onset of symptoms, vascular risk factors for ED, patient estimated degree of deformity, and patient assessment of quality of erection with respect to rigidity.
- Validated questionnaires include the PDQ to document the degree of effect associated with PD.
- The physical examination focuses on palpability of plaque with the penis on stretch to enhance appreciation of plaque, stretched flaccid penile length, and presence of pain during palpation.
- Deformity (e.g., curve, indentation) is assessed during a vasoactive drug injection–induced erection using goniometer and duplex ultrasound, particularly for assessment of plaque mineralization and especially if surgery is contemplated.

NONSURGICAL TREATMENT OF PEYRONIE DISEASE

Myriad nonsurgical treatments for PD have been offered since the time of de la Peyronie. Medical therapy until very recently has been compromised by suboptimal studies that failed to demonstrate meaningful results owing to small numbers of subjects, lack of a control group, lack of randomization, and limited objective measurements (Schaeffer and Burnett, 2012). In addition, the variety of disease presentations and its poorly understood cause contribute to treatments that have not addressed the underlying pathophysiology of this wound-healing disorder. In this section, we review the contemporary treatments and focus on placebo-controlled studies when possible.

Some patients require only reassurance, particularly if there is no difficulty or pain for the patient or his partner in accomplishing penetrative sex. Patients should also be reassured that this is not a disorder that will degenerate into a cancer and is therefore not life-threatening.

TREATMENT PROTOCOLS

Multiple treatment protocols have been developed and published. It should be recognized that these algorithms serve only as guidelines and that individualization is key to patient success, which depends on specific findings from the history, physical examination, duplex ultrasonography, and patient goals (Levine and Lenting, 1997; Levine and Greenfield, 2003; Bokarica et al, 2005; Ralph et al, 2010; Hatzimouratidis et al, 2012).

Oral Medications**Potaba**

Potassium aminobenzoate (Potaba) is a member of the vitamin B complex. Its mechanism of action has not been studied since 1959, when Zarafonitis and Horrax demonstrated in fibroblast cell cultures that potassium aminobenzoate can reduce the formation of collagen. According to this in vitro study, it is believed that this drug decreases serotonin levels by increasing monoamine oxidase

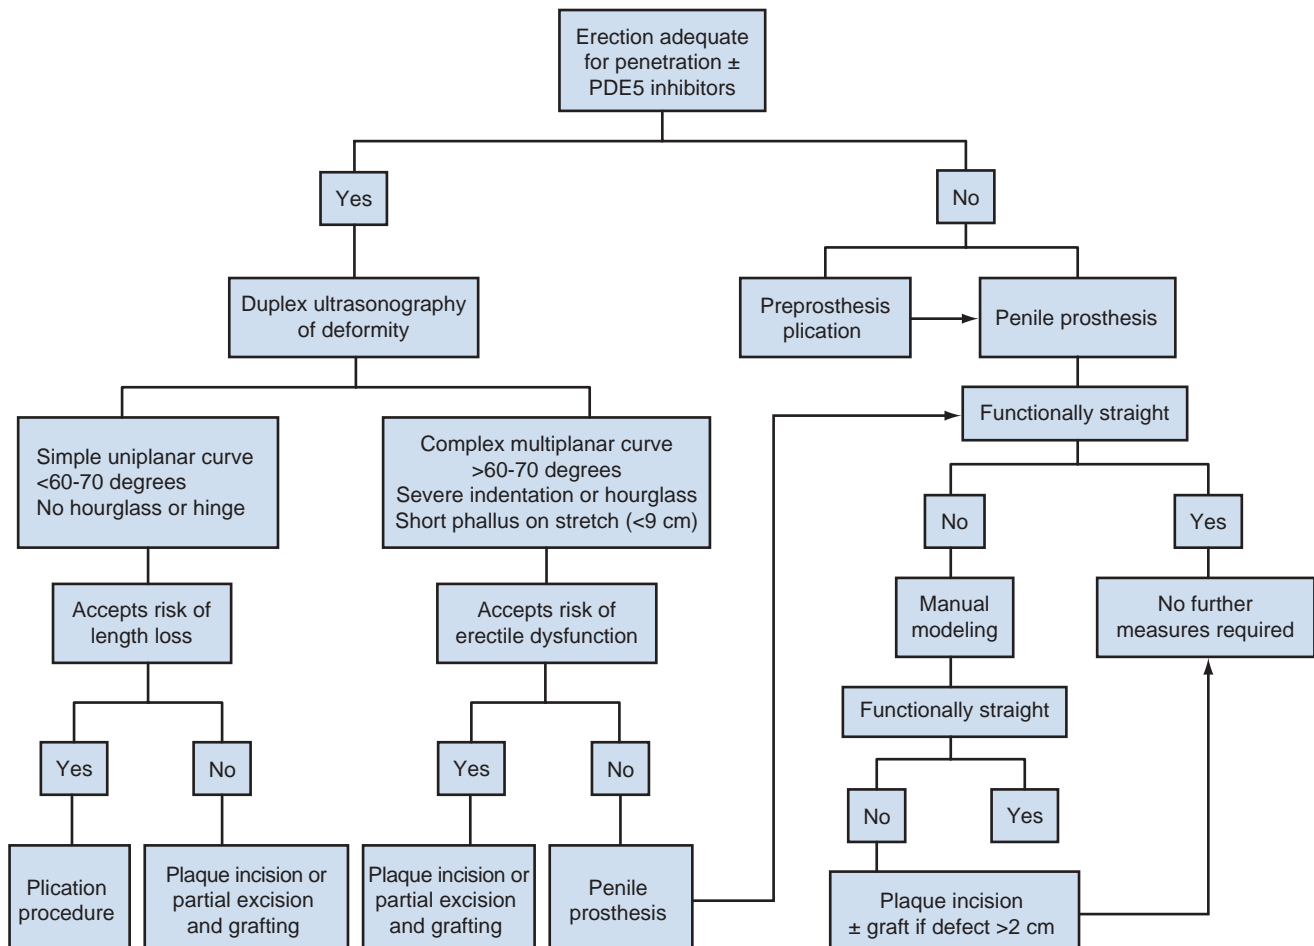

Figure 31-10. Algorithm for the surgical management of Peyronie disease. PDE5, phosphodiesterase type 5.

activity, resulting in enhancement of the endogenous antifibrotic properties of tissues (Zarafonitis and Horrax, 1959).

In a randomized double-blind placebo-controlled trial of 103 treatment-naïve PD patients with noncalcified plaque, 51 patients were assigned to treatment with potassium *p*-aminobenzoate and 52 to placebo. Mean plaque size decreased in the treatment arm, whereas plaque size remained stable over 12 months of follow-up in the placebo arm. Penile deviation remained stable in those receiving active drug; penile curvature deteriorated significantly in 32.5% of those receiving placebo. No significant differences concerning decrease in pain could be observed between the two groups. The authors concluded, "Potassium paraaminobenzoate appears to be useful to stabilize the disorder and prevent progression of penile curvature" (Weidner et al, 2005). No severe adverse events occurred in the study; however, acute hepatitis associated with administration of potassium aminobenzoate for PD has been reported (Roy and Carrier, 2008). Because there is little evidence of benefit with potassium amino benzoate in placebo-controlled trials and it is expensive and difficult to consume (24 tablets daily), we do not recommend its use.

Vitamin E

Vitamin E is one of the oldest described oral treatments for the treatment of PD (Scardino and Scott, 1949). Vitamin E, a fat-soluble vitamin metabolized in the liver and excreted in bile, is an antioxidant that is thought to limit oxidative stress of ROSs known to be increased during the acute and proliferative phases of wound healing. Increased free-radical expression and a prolonged inflammatory phase of wound healing have been demonstrated in PD. Treatment with vitamin E inactivates circulating free radicals that otherwise would inhibit NO from exerting its positive effects on vascular smooth muscle (Safarinejad et al, 2007).

Several well-designed studies have demonstrated no significant improvement in pain, curvature, and plaque size when compared with placebo (Ralph et al, 2010). Pryor and Farrell (1983) conducted a double-blind, placebo-controlled crossover study evaluating vitamin E for the treatment of PD in 40 subjects. No significant improvements were noted in plaque size or penile curvature (Pryor and Farrell, 1983). Gelbard and associates (1990) compared treatment with vitamin E with the natural history of PD in 97 subjects with disease duration ranging from 3 months to 8 years; no significant differences were found between the two groups in terms of curvature, pain, or the ability to have intercourse (Gelbard et al, 1990). In a randomized double-blind placebo-controlled study of a total of 236 men with PD, vitamin E failed to show benefit with respect to pain, curvature, or plaque size when compared with placebo (Safarinejad et al, 2007). Although there were no significant observed adverse effects reported in this study, there is evidence that vitamin E may increase the risk of cerebrovascular events (Brown et al, 2001). Vitamin E is the most frequently recommended oral agent in spite of studies showing no benefit over placebo (LaRochelle and Levine, 2007; Shindel et al, 2008).

Tamoxifen

Tamoxifen is a selective estrogen receptor modulator that has both agonist and antagonist effects on target tissues depending on tissue-specific estrogen receptor expression. It has also been demonstrated that tamoxifen can induce the production of TGF- β in an estrogen receptor-independent fashion (Colletta et al, 1990). The use of tamoxifen for the treatment of PD is truly fascinating and underscores how complex the role of TGF- β is in the development of PD. TGF- β released by platelets and activated macrophages plays a central role in the inflammatory response and wound healing. In normal healing it promotes matrix synthesis by fibroblasts and is self-regulated in an autocrine fashion. However, higher concentrations of TGF- β in the cellular environment inhibit the inflammatory response, causing macrophage deactivation and T-lymphocyte suppression, thus preventing further fibrogenesis (Wahl et al, 1989). This was the initial reasoning for Ralph and associates (1992) to

report in a nonrandomized study on the initial use of tamoxifen for the treatment of PD (Ralph et al, 1992).

The initial beneficial effects previously reported were not confirmed in a randomized placebo-controlled trial of 25 patients with PD (Teloken et al, 1999). The study demonstrated no significant improvement with respect to pain, penile deformity, or plaque size when compared with placebo (Teloken et al, 1999).

Colchicine

Colchicine has been demonstrated to have several different potential mechanisms of action in the treatment of PD. By binding to tubulin and causing it to depolymerize, colchicine inhibits cell mitosis, mobility, and adhesion of leukocytes; inhibits transcellular movement of collagen; and stimulates the production of collagenase (Taylor, 1965; Ehrlich and Bornstein, 1972; El-Sakka et al, 1999).

In a randomized double-blind placebo-controlled study to determine the effectiveness and safety of colchicine, 84 PD patients with noncalcified plaque were randomized to colchicine or placebo. Objective measurements did not demonstrate any difference in plaque size or penile curvature. There were no substantial differences in response to treatment based on duration of disease or within the three Kelami classification groups (Kelami, 1983). Significant drug-related adverse effects in the colchicine group included gastrointestinal upset with diarrhea (Safarinejad, 2004).

Carnitine

Carnitine is a trimethylamine molecule that plays a unique role in cell energy metabolism (Reda et al, 2003). L-Carnitine is hypothesized to act by increasing mitochondrial respiration and decreasing free radical formation (Bremer, 1983).

In the same double-blind placebo-controlled study mentioned previously, Safarinejad and colleagues compared the effects of L-carnitine with placebo (Safarinejad et al, 2007). Fifty-nine PD patients were randomized to receive propionyl-L-carnitine and 59 were randomized to placebo during the 6-month treatment period. This study again did not show significant improvement in pain, curvature, or plaque size in patients with PD treated with propionyl-L-carnitine as compared with those treated with placebo.

Pentoxifylline

Pentoxifylline has been shown to block the TGF- β 1-mediated pathway of inflammation and to prevent deposition of collagen type I and is a nonspecific phosphodiesterase inhibitor with combined anti-inflammatory and antifibrogenic properties. In an animal model of PD, pentoxifylline reduced the expression of collagen I, α -smooth muscle actin (ASMA), and plaque size by 95% (Valente et al, 2003). Pentoxifylline inhibits tunica albuginea-derived fibroblast proliferation in vitro and attenuates TGF- β -mediated elastogenesis and collagen type I deposition (Shindel et al, 2010). Elastogenesis is inhibited not by decreasing the amount of elastin produced but by inhibiting its deposition through an α_1 -antitrypsin-related mechanism (Lin et al, 2010). Pentoxifylline has also been shown to downregulate TGF- β and increases fibrinolytic activity (Schandené et al, 1992; Raetsch et al, 2002). Pentoxifylline has been used successfully for the treatment of experimental autoimmune diseases, the presence of which has been suggested as a cause of PD (Ralph et al, 1996). Pentoxifylline downregulates the release and the production of the profibrotic cytokine tumor necrosis factor (TNF), suppresses the production of platelet-activating factor, and inhibits its action on neutrophils (Safarinejad et al, 2010).

In a randomized double-blind placebo-controlled study, 114 PD patients were randomized to receive pentoxifylline and 114 were randomized to placebo for 6 months. Of patients in the pentoxifylline group, 12 (11%) had disease progression, versus 46 (42%) in the placebo group. Improvement in penile curvature and plaque volume was significantly greater in patients treated with

pentoxifylline than with placebo. The increase in International Index of Erectile Function (IIEF) total score was significantly higher in the pentoxifylline group. One patient discontinued the medication because of adverse effects. There were no adverse effects in any of the vital signs or in the laboratory data. Pentoxifylline is a peripheral vasodilator and could induce hypotension; consequently, blood pressure should be monitored during treatment with this drug. The most common side effects include nausea, vomiting, dyspepsia, malaise, flushing, dizziness, and headache (Safarinejad et al, 2010).

Phosphodiesterase Type 5 Inhibitors

PDE5 inhibitors have been shown to be safe and effective in treating ED in patients with PD (Levine and Latchamsetty, 2002). Recently tadalafil was shown to significantly improve IIEF and quality-of-life (QoL) scores when used in conjunction with extracorporeal shock-wave therapy (ESWT) as compared with ESWT alone (Palmieri et al, 2012). There was no advantage with respect to deformity.

PDE5 inhibitors have also been suggested as treatment for PD. By increasing the levels of cGMP, PDE5 inhibitors can inhibit collagen synthesis and induce fibroblast and myofibroblast apoptosis, thus acting as antifibrotic agents by inhibiting scar development (Valente et al, 2003; Gonzalez-Cadavid and Rajfer, 2010).

In a study by Chung and associates (2001), 35 men with an isolated septal scar received tadalafil 2.5 mg daily over a 6-month period, after which 24 patients (69%) had resolution of the septal scar. The authors concluded that low-dose daily tadalafil is a safe and effective treatment option in septal scar remodeling (Chung et al, 2011a).

Intralesional Injection

Verapamil

Calcium channel blockers were originally found to inhibit the incorporation of proline into ECM protein, thus leading to the conclusions that cellular calcium metabolism appears to regulate ECM production and that hypertrophic disorders of wound healing may respond to therapy with calcium channel antagonist drugs (Lee and Ping, 1990).

Verapamil is a calcium channel blocker that has been shown to significantly affect fibroblast function on several levels, including cell proliferation, ECM protein synthesis and secretion, and collagen degradation. In vitro Peyronie plaque fibroblast proliferation is inhibited by 65% by verapamil at a concentration of 100 to 1000 mg/mL (Anderson et al, 2000). These changes may allow intralesional verapamil to retard, prevent, or possibly reverse plaque formation and progression of PD (Levine and Estrada, 2002). Recently a study demonstrated the mechanism of action of intralesional verapamil injection versus normal saline in a rat model. After verapamil injection there were histologic changes as well as reduced plaque size and penile curvature. Verapamil injection also resulted in decreased collagen and elastin fibers, as well as reduced ASMA, an indicator of myofibroblast activity (Chung et al, 2013b).

The first reported use of verapamil for the treatment of PD was by Levine and associates and was the first new intralesional treatment since steroid injection was introduced in 1957 (Furey, 1957; Levine et al, 1994). This was a nonrandomized dose-escalating study in 14 men who received biweekly injections of verapamil for 6 months. Subjectively, there was significant improvement in plaque-associated penile narrowing (100%) and curvature (42%). Objectively, a decreased plaque volume of more than 50% was noted in 30% of the subjects. Plaque softening was noted in all patients, and 83% noticed that plaque-related changes in erectile function had arrested or improved. There was no toxicity, nor did symptoms recur when improvement was noted. This preliminary study suggested that intralesional verapamil may be an economical and sensible nonoperative approach to the treatment of PD warranting further study (Levine et al, 1994). In a larger noncontrolled study, verapamil injection resulted in a reduction of pain in 97%

of the patients, an improvement in sexual function in 72%, a subjective reduction of deformity in 86%, an improvement in distal rigidity in 93%, and an objective reduction of curvature in 54% (mean curve reduction of 25 degrees) (Levine, 1997).

Rehman and associates (1998) performed a single-blind study on 14 PD patients who were randomly assigned to injection with verapamil or saline. This study demonstrated a significant improvement in plaque size, plaque-associated penile narrowing, and quality of erection in the verapamil-treated men versus the control group. There was no significant difference with respect to penile curvature. There was no local or systemic toxicity except for an occasional ecchymosis or bruise at the injection site (Rehman et al, 1998). Bennett and colleagues showed in a shorter 3-month trial of 94 patients improvement in curvature in 18%, no change in 60%, and worsening in 22% and concluded that intralesional verapamil can at a minimum stabilize penile deformity (Bennett et al, 2007).

Currently, intralesional verapamil is one of the leading treatment options for the conservative management of PD despite the fact that some studies have not shown as favorable a response as described earlier (Shindel et al, 2008). In a recent randomized single-blind placebo-controlled trial, Shirazi and associates (2009) randomized 80 patients to receive intralesional verapamil and 40 patients to receive local saline injection. This study demonstrated no significant difference with respect to plaque size, pain, curvature, plaque softening, or improvement in sexual dysfunction in the active drug and control groups. This study concluded that although some trials have demonstrated intralesional verapamil to be an effective treatment for PD, further larger-scale studies are warranted given these negative findings to assess the effectiveness of intralesional verapamil for the treatment of PD (Shirazi et al, 2009). This study highlights the potential for inconsistent results for men with PD, which may vary because of patient selection, presence of calcification, plaque location, drug administration technique, and sample size. Drug concentration has also been evaluated, and although 10 mg/10 mL is the most commonly used dose and volume, Cavallini and associates (2007) showed a greater response to injection when 10 mg of verapamil was diluted with 20 mL of injectable saline (Cavallini et al, 2007). Poor candidates for this treatment include those with extensive calcification, curvature of greater than 90 degrees, or ventral curvature, in which it is difficult to adequately infiltrate the plaque (Levine et al, 2002). Predictors of success with intralesional verapamil include younger age (below age 40) and curvature greater than 30 degrees (Moskovic et al, 2011).

Nicardipine

Nicardipine is a dihydropyridine (DHP) type of calcium channel blocker. An in vitro study has suggested that it is more effective than a non-DHP type, verapamil, in reducing glycosaminoglycan biosynthesis and ECM production (Gürdal et al, 1992). Soh and associates (2010) performed the only study on the effectiveness of nicardipine for the treatment of PD. A total of 74 patients were assigned randomly to nicardipine versus saline. Nicardipine demonstrated a significant reduction of pain, improvement in IIEF-5 score, and reduction of plaque size when compared with placebo. Penile curvature was significantly improved in both the active drug and placebo groups without significant difference. There were no severe side effects, such as hypotension or other cardiovascular events (Soh et al, 2010).

Interferon Alfa-2b

IFN alfa-2b was first investigated as a treatment for PD in 1991 in the in vitro studies by Duncan and associates (1991). In fibroblasts derived from Peyronie plaques, the addition of IFN alfa-2b decreased their rate of proliferation in a dose-dependent fashion, decreased the production of extracellular collagen, and increased the production of collagenase (Duncan et al, 1991).

In a single-blind, multicenter, placebo-controlled, parallel study to assess the safety and efficacy of intralesional IFN alfa-2b,

Hellstrom and associates (2006) randomized a total of 117 consecutive PD patients to IFN alfa-2b or saline. Improvement in penile curvature, plaque size and density, and pain resolution was significantly greater in patients treated with IFN alfa-2b versus placebo. The treatment group demonstrated a mean decrease in curvature of 27% or 13.5 degrees versus 9% or 4.5 degrees in the placebo group. Although these results were statistically significant, the question arises whether the small difference between the IFN and saline is clinically significant when taking into account the significant cost of the drug and its side effect profile, which frequently includes flulike symptoms (fever, chills, and arthralgia) and minor penile swelling with ecchymosis. All these symptoms were effectively treated with over-the-counter nonsteroidal anti-inflammatory agents ingested before the injection procedure, and none lasted longer than 36 hours (Hellstrom et al, 2006). This study was important because it was the first multicenter randomized placebo-controlled trial of intralesional injection for PD. It also was important because it showed that saline injection had little to no effect on penile deformity.

Clostridial Collagenase

The first U.S. Food and Drug Administration (FDA)-approved drug for the treatment of PD, collagenase *Clostridium histolyticum* (CCH), is produced by the bacterium *C. histolyticum* and selectively degrades collagen types I and III in connective tissues despite the presence of TIMPs, which have been shown to be elevated in PD as well as to increase apoptosis of fibroblasts (Morales et al, 1983; Matsushita et al, 2001; Del Carlo et al, 2008; Syed et al, 2012). The recent flurry of investigation on this drug has come many years after the first time it was examined as a treatment for PD by Gelbard and associates (1982), who demonstrated that CCH significantly reduced the size of PD plaques, whereas elastic fibers, vascular smooth muscle, and axonal sheaths were not affected (Gelbard et al, 1982).

In the first prospective, randomized, double-blind, placebo-controlled study of CCH, 49 men with PD were treated with CCH, resulting in significant improvements in plaque size and penile deformity (Gelbard et al, 1993). All patients with a penile bend of 30 degrees or less and/or palpable plaque less than 2 cm responded ($N = 3$); 36% of patients with a penile bend of 30 to 60 degrees and/or 2 to 4 cm of palpable plaque responded; and 13% of patients with a penile bend of greater than 60 degrees and/or greater than 4 cm of palpable plaque responded. CCH was well tolerated, with no allergic reactions and no significant changes in laboratory parameters (Gelbard et al, 1993). Further investigation was encouraged but took years owing to absence of industry support.

In a phase 2 trial, 25 patients with PD received three intralesional injections of 10,000 units of CCH over 7 to 10 days, with a repeat of treatment at 3 months to assess change from baseline in penile deviation angle and plaque size (Jordan, 2008). A decrease in deviation angle of at least 25% was achieved in 58% of patients, and 95% of patients experienced a reduction in plaque size (Jordan, 2008). More than 50% of patients in this series were considered "very much improved" or "much improved" at all time points in the study; approximately one third were considered to show minimal improvement or no change, resulting in an investigator's assessment of "worse."

In a phase 2b trial, 147 patients with PD were enrolled in a randomized, double-blind, placebo-controlled trial of CCH or placebo, with a second randomization to modeling or nonmodeling (Gelbard et al, 2012). Patients receiving CCH and modeling had a significant change in curvature of the penis and decrease in the PD symptom effect score compared with placebo (Gelbard et al, 2012).

The phase 3 IMPRESS (Investigation for Maximal Peyronie Reduction Efficacy and Safety Studies) I and II trials examined the clinical efficacy and safety of CCH intralesional injections in subjects with PD (Gelbard et al, 2013). A total of 417 and 415 subjects, respectively, went through a maximum of four treatment cycles, each separated by 6 weeks. Men received up to eight injections of

0.58 mg CCH, two injections per cycle separated by approximately 24 to 72 hours with the second injection of each followed 24 to 72 hours later by penile plaque modeling. Men were stratified by baseline penile curvature (30 to 60 degrees versus 61 to 90 degrees) and randomized to CCH or placebo 2:1 in favor of active drug. Post hoc meta-analysis of IMPRESS I and II data revealed that men treated with CCH showed a mean 34% improvement in penile curvature, representing a mean change of -17.0 degrees ± 14.8 degrees per subject, compared with a mean 18.2% improvement in placebo-treated men, representing a mean change of -9.3 ± 13.6 degrees per subject ($P < .0001$). The mean change in PD symptom effect score was significantly improved in treated men versus men on placebo (-2.8 ± 3.8 vs. -1.8 ± 3.5 , $P = .0037$). Patients with extensive calcification, ventral plaques, and disease duration less than 12 months were excluded. Although serum antibodies to CCH developed in virtually all patients studied, no adverse events were noted as a result. The primary and frequently noted side effect was varying degree of ecchymosis and local penile bruising. Serious adverse events included corporeal rupture in three patients and penile hematoma in three patients. All three corporeal ruptures and one of the three penile hematomas were successfully repaired surgically; another hematoma was successfully drained percutaneously (Gelbard et al, 2013). Further experience will help determine which patients may benefit most from CCH. This may depend on direction of curve, size of plaque, prevalence of calcification, and duration of disease, among other factors to be determined. A recent presentation did demonstrate that surgical correction with plication or grafting could be successfully performed after CCH injection without added technical difficulty (Larsen and Levine, 2012). CCH received FDA approval for the treatment of PD in December 2013.

Topical Drug Application

Several studies have evaluated the effectiveness of topically applied agents for the treatment of PD. Topical application avoids the pain and trauma of intralesional injection therapy. The first study of topical application of a drug, β -aminopropionitrile, showed no benefit with respect to deformity change (Gelbard et al, 1983).

Topically applied liposomal recombinant human superoxide dismutase (IrhSOD) has also been studied in a randomized placebo-controlled trial (Riedl et al, 2005). This substance is proposed to act as an oxygen free radical scavenger, which might interrupt inflammatory cascades and thereby limit further disease progression. Penile curvature was improved by 5 to 30 degrees in 23% of patients and pain was significantly reduced as well ($P = .017$) compared with placebo after 4 weeks. The authors concluded that IrhSOD is an easily given, safe, and effective local therapeutic for the painful phase of PD (Riedl et al, 2005). No further studies have been performed regarding the use of IrhSOD. Therefore at this time the data are insufficient to recommend its use.

Fitch and associates (2007) reported on the use of topical verapamil for the treatment of PD (Fitch et al, 2007). Two simultaneous three-armed, double-blind, placebo-controlled studies were conducted in this pilot study. In this study topical verapamil improved curvature in 14 of 18 patients (77.8%) with mean curvature improvement of 43.6%. This study also boasted reduction in plaque size in 100% of participants, as well as improvement in erectile function in 72.7%. This study was originally aimed at comparing verapamil to topical trifluoperazine, but because of the severity of side effects (anxiety, agitation, blurred vision, insomnia, and depression), topical trifluoperazine was discontinued before completion of randomization. The results of this study have been called into question given the small sample size, lack of a true placebo, and absence of objective measures (Levine, 2007). In addition, simple topical administration of verapamil has been shown to be ineffective in achieving tissue levels within the tunica albuginea sufficient for therapeutic effect (Martin et al, 2002).

At this time, no topically applied agent has been shown to be effective in the treatment of PD.

Electromotive Drug Administration

Transdermal drug delivery was proposed to be superior to oral or injection therapy because it bypasses hepatic metabolism and minimizes the pain of injection. Unlike topical verapamil gel, electromotive drug administration (EMDA) with verapamil has been found to deliver detectable levels of the drug to the tunica albuginea (Martin et al, 2002; Levine et al, 2003).

A double-blind, placebo-controlled trial to determine the effectiveness of verapamil delivered through EMDA randomized a total of 42 PD patients to verapamil versus saline. Treatments were performed twice weekly for 3 months. Both verapamil and saline groups demonstrated essentially equivalent reduction of curvature. The study concluded that further research is necessary to determine whether electric current alone may have a role in the treatment of PD (Greenfield et al, 2007). Overall, EMDA was well tolerated in each group and it was noted by all patients to be easy and convenient to perform at home. The only adverse event reported by patients was temporary mild erythema at the treatment site (Greenfield et al, 2007).

In another prospective placebo-controlled study with transdermal EMDA, Di Stasi and associates (2004) randomized patients to receive verapamil and dexamethasone versus placebo. Those receiving active drug demonstrated significant decreases in plaque volume as well as penile curvature from 43 degrees to 21 degrees, which was significant when compared with placebo. Significant pain relief occurred in both groups, transient in the control group and permanent in the study group. All patients experienced temporary erythema at the electrode site. There were no other side effects (Di Stasi et al, 2004). Although this approach has limited evidence of benefit, it has not been adopted in most centers.

Extracorporeal Shockwave Therapy

The mechanism of action involved in ESWT for PD is unclear. However, there are two purported hypotheses: (1) Shock waves cause direct damage to the penile plaque, and (2) ESWT increases the vascularity of the targeted area by generating heat, which leads to the induction of an inflammatory reaction, resulting in lysis of the plaque and removal by macrophages (Gholami et al, 2003).

In the first prospective randomized double-blind placebo-controlled clinical trial evaluating ESWT for the treatment of PD, 100 treatment-naïve PD patients with disease duration less than 12 months were randomly allocated to either ESWT ($n = 50$) or placebo ($n = 50$). For the placebo group, a nonfunctioning transducer was employed. Patients randomized to ESWT demonstrated improvements in pain, IIEF-5 score, and mean QoL score. Plaque size and penile curvature were not significantly different in the treatment and placebo groups. After 24 weeks, mean IIEF-5 score and mean QoL score were stable in the ESWT group, whereas mean visual analog scale (VAS) score was significantly lower when compared with baseline in both groups. It is interesting to note that after 24 weeks, mean plaque size and mean curvature degree were significantly worse in the placebo group when compared with both baseline and ESWT values. This difference was less than 3 degrees, which, although statistically significant, is of no clinical significance (Palmieri et al, 2012).

Recently a second placebo-controlled, prospective randomized single-blind study was performed in which 102 PD patients were randomly assigned ($n=51$) to ESWT or placebo (Hatzichristodoulou et al, 2013). Pain decreased in 17 of 20 (85.0%) patients in the ESWT group and in 12 of 25 (48.0%) patients in the placebo group. Penile deviation was not reduced by ESWT and worsened in 40% and 24.5% of patients in the ESWT and placebo groups, respectively ($P=.133$). Change in sexual function and plaque size reduction was not different between the two groups. In addition, plaque size increased in five patients (10.9%) receiving ESWT only. The authors concluded that despite some potential benefit of ESWT with regard to pain reduction, it should be emphasized that pain usually resolves spontaneously with time. Given this and the fact

that deviation may worsen with ESWT, the treatment cannot be recommended.

Penile Traction

Controlled stretching of the penis, or "penile traction," by a device that holds the penis in a cradle and subjects it to tension appears to meet a previously unmet need within the population of PD patients for a noninvasive, nonsurgical first-option treatment modality.

Traction has been shown in nonpenile tissue models to induce cellular proliferation by several pathways (Ilizarov, 1989; Sun et al, 1996; Molea et al, 1999; Assoian and Klein, 2008; Bueno and Shah, 2008). It can also trigger scar remodeling; it has been shown that tension applied to tissues leads to a reorientation of collagen fibrils parallel to the axis of stress (Molea et al, 1999; Shapiro, 2008). These changes are the result of a process referred to as *mechanotransduction* whereby mechanical stimuli are converted into chemical responses within the cell (Alenghat and Ingber, 2002). Several signaling cascades are activated by tension on the cytoskeleton, which leads to a proliferative response as well as activation of various genes (Assoian and Klein, 2008). An *in vitro* study to determine the cellular effects of traction on PD cells demonstrated a significant decrease in ASMA in the strained compared with nonstrained PD cell cultures, whereas an increase in MMPs involved in collagen degradation was observed. In contrast, cytokines and proteins involved in fibroblast replication and inflammation such as ASMA, heat shock protein 47 (HSP47), and TGF- β 1 receptor were not upregulated (Chung et al, 2013a). Several studies have been performed examining the clinical effects of traction for the treatment of PD, although none have been controlled trials.

Levine and associates (2008) first demonstrated the use of penile traction for the treatment of PD in a pilot study of 10 men. In nearly all (90%), prior medical therapy had failed. Traction was applied as the only treatment for 2 to 8 hr/day for 6 months. All subjects underwent pretreatment and post-treatment physical examination including measurement of stretched flaccid penile length and biotensiometry. Subjectively, all men noted reduced curvature estimated at 10 to 40 degrees, increased penile length (1 to 2.5 cm), and enhanced girth in areas of indentation or narrowing. Objective measures demonstrated reduced curvature in all 10 men of up to 45 degrees; average reduction for the group was 33%, from 51 degrees to 34 degrees. SPL increased 0.5 to 2.0 cm, and erect girth increased 0.5 to 1.0 cm with correction of hinge effect in four out of four men. It is important to note that results were maintained at 6 months after completion of therapy. The IIEF erectile function domain score increased from 18.3 to 23.6 for the group. There were no adverse events including skin changes, ulcerations, hypoesthesia, or diminished rigidity (Levine et al, 2008).

Gontero and associates (2009) performed a phase 2 prospective study on 15 PD patients with a curvature not exceeding 50 degrees with mild or no ED. Penile curvature decreased from an average of 31 degrees to 27 degrees at 6 months, which was not statistically significant. Mean stretched and flaccid penile length increased by 1.3 and 0.83 cm, respectively, at 6 months. Results were maintained at 12 months. Overall treatment results were subjectively scored as acceptable in spite of limited curvature improvements, which varied from "no change" to "mild improvement." The investigators concluded that the use of a penile extender device provided only minimal improvements in penile curvature but a reasonable level of patient satisfaction, probably attributable to increased penile length. The selection of patients with stabilized disease, many with calcified plaques, and penile curvature not exceeding 50 degrees may have led to outcomes underestimating the potential efficacy of the treatment (Gontero et al, 2009).

Recently a prospective nonrandomized study was conducted administering traction to PD patients in the acute phase, defined as progressive penile curvature exceeding 15 degrees and/or pain at rest or at erection in the last 12 months (Martínez-Salamanca et al, 2014). A total of 55 patients underwent traction for 6 months and were compared with 41 patients also in the acute phase who did

not. Patients were advised to use the device at least 6 hours a day and no more than 9 hours, preventing its use during sleep. Mean duration of use was 4.6 hours per day (3.1 to 9.2 hours). Also, patients were taught to remove the device for at least 30 minutes every 2 hours to prevent glans ischemia. **The mean curvature decreased from 33 degrees at baseline to 15 degrees at 6 months and 13 degrees at 9 months with a mean decrease of 20 degrees in the traction group.** VAS score for pain decreased from 5.5 to 2.5 after 6 months ($P < .05$). The percentage of patients who were not able to achieve penetration decreased from 62% to 20% ($P < .03$). Without this intervention, deformity increased significantly, stretched flaccid penile length decreased, VAS score for pain increased, and erection hardness worsened. **Furthermore, the need for surgery was reduced in 40% of patients who would otherwise have been candidates for surgery and simplified the complexity of the surgical procedure (from grafting to plication) in one of every three patients.** Treatment-related adverse events included two cases of erythema in the balanopreputial sulcus, which resolved with stopping traction for 24 to 48 hours. Fourteen patients (25.5%) reported some degree of discomfort. Worsening of erectile function over the treatment period was not observed, **and the overall satisfaction rate was 85% (range 60% to 90%) at 9 months.** No case of sensory change after traction was reported (Martínez-Salamanca et al, 2014). **In our opinion, traction therapy has the potential to be the most effective nonsurgical treatment to recover lost length, reduce curvature, and enhance girth.** It is critical that the patient wear the device for 3 or more hours per day to get satisfactory results.

Vacuum Therapy

Application of a penile vacuum device to mechanically straighten the penis has been evaluated in one published noncontrolled study in which subjects wore the vacuum device for 10 minutes twice per day for 12 weeks. This study demonstrated a reduction in the angle of curvature by 5 degrees to 25 degrees in 21 of 31 patients. Three patients' curvature worsened, and in seven the curvature remained unchanged. Fifty-one percent were satisfied with this outcome; the other 49% went on to surgical correction (Raheem et al, 2010). Although vacuum erection devices are usually considered safe, it would seem that the short-term duration of stretching forces on the penis would not induce the desired physical changes known to occur with mechanotransduction with prolonged stretch therapy. Several complications such as the development of PD, urethral bleeding, skin necrosis, and penile ecchymosis have been reported with concomitant use of constriction rings and when inappropriately elevated pressures are applied to the penis for an extended period of time (Kim et al, 1993; Ganem et al, 1998).

Combination Therapy

One study investigated whether the combination of the mechanical effects of penile traction with the chemical effects of intralesional verapamil and oral medications (pentoxifylline and L-arginine) could have a synergistic effect on the tunica albuginea and Peyronie plaque (Abern et al, 2012). All patients were given oral pentoxifylline and L-arginine, with 39 electing to undergo traction and 35 choosing not to use traction. Both treatment groups had a statistically significant reduction in erect penile curvature. The traction group had a reduction from a mean of 44.4 degrees (standard deviation [SD] 27.5 degrees) at baseline to a mean of 33.4 degrees (SD 25.3 degrees) after the 24-week protocol ($P = .03$). Patients not using traction had a reduction from a mean of 36.6 degrees at baseline (SD 18.5 degrees) to a mean of 21.5 degrees (SD 19.3 degrees) after treatment ($P < .01$). There were no statistically significant differences in curvature outcomes between the two groups. In patients using traction, SPL increased overall by a mean 0.3 cm (SD 0.9 cm) after treatment, which trended toward statistical significance ($P = .06$), whereas the men not using traction lost an average of 0.7 cm (SD 1.1 cm) of length, which was not statistically different ($P = .46$) (Abern et al, 2012). Unfortunately, this

study did not control for duration of traction therapy, and some men included in the traction group applied the device for only 1 to 2 hr/wk, whereas others wore it for over 50 hr/wk. An analysis of traction duration and deformity change demonstrated that wearing the device on average three or more hours per day allowed reliable measured deformity improvement, which occurred in a dose-response fashion.

Another combination study examined the effects of combining verapamil injection and verapamil iontophoresis with or without the use of a combination pill that contained vitamin E (36 mg), *p*-aminobenzoic acid (100 mg), propolis (as galangin 100 mg), blueberry anthocyanins (80 mg), soy isoflavones (50 mg), *Muirapauama* (25 mg), damiana (25 mg), and *Persea americana* (50 mg). Intergroup analysis revealed greater plaque size reduction (−30.8% vs. −18.0%) and greater percentage with reduction of curvature (85% vs. 53.5%) with use of the combination pill (Paulis et al, 2013b).

Radiation Therapy

Radiation therapy has been proposed as a treatment for PD since 1964 (Duggan, 1964). **In vitro studies suggest that low-dose radiation therapy has a potent anti-inflammatory effect, inhibiting leukocyte-endothelium interactions** (Arenas et al, 2012). In recent years, radiation therapy has been proposed as a treatment for pain that was thought to be "abnormally persistent." In 1975 a retrospective study examined the use of radiation therapy and found it to be no more effective than no treatment (Incrocci et al, 2000). **It is the consensus of multiple experts in the field that radiation should be avoided because of potential risk of malignant change and increase in the risk of ED in aging patients** (Ralph et al, 2010; Hatzimouratidis et al, 2012; Mulhall et al, 2012).

Conclusion

At this time it is our opinion that combination therapy will offer the best opportunity for improvement by creating a synergy between the chemical effects of the oral and/or injectable agents and the mechanical effects of external forces on the penis. The recent addition of an FDA-approved treatment (injectable CCH) provides what appears to be a sensible nonsurgical treatment option for PD. Further experience will allow better discrimination as to the optimum candidates. Clearly, it appears that the goal of nonsurgical treatment at a minimum should be to prevent progression of deformity during the acute phase. Reducing deformity to improve sexual function and reduce the effects of the scarring is the ultimate goal of all treatment for PD (Tables 31-1, 31-2, and 31-3).

SURGICAL MANAGEMENT

Indications

Surgical reconstruction is indicated for men with deformity that precludes satisfactory sexual intercourse or causes pain for themselves or their partner during sexual relations or because of distress as a result of the appearance of the erect penis (Kadioglu et al, 2006).

Surgery remains the gold standard treatment to most rapidly and reliably correct the deformity associated with PD; and for men who also have ED, placement of a penile prosthesis can provide rigidity for penetrative sexual activity. The indications for surgical correction include stable disease, which is defined as disease that is at least 1 year from onset, and at least 6 months of stable deformity. These indications have not been formally studied but appear to be generally accepted by experts in the field (Jordan, 2007; Ralph et al, 2010; Levine and Burnett, 2013). Other indications include a deformity that compromises or makes impossible the patient's ability to engage in sexual intercourse because of the nature of the deformity and/or inadequate rigidity, and patients in whom conservative therapy has failed (Box 31-4). No single surgical approach is universally defined as the

KEY POINTS: NONSURGICAL TREATMENT OF PEYRONIE DISEASE

- Patients who have no pain or difficulty in accomplishing penetrative sex may require only reassurance, because this is not a disorder that will degenerate into a cancer and is not life-threatening.
- A poor understanding of the cause of this wound-healing disorder contributes to the fact that to date, conservative treatments often yield inconsistent and clinically insignificant improvements in deformity.
- Currently, no oral agent has been shown in placebo-controlled trials to result in clinically meaningful improvement in curvature.
- Topical therapy and ESWT have not been shown to reduce penile deformity.
- Intravesical verapamil and IFN alfa-2b have shown evidence of reduced curvature and improved sexual function. Yet most studies are not controlled trials. These agents at a minimum appear to result in deformity stabilization during the acute phase.
- The first FDA-approved drug for the treatment of PD, CCH is produced by the bacterium *C. histolyticum* and selectively degrades collagen types I and III. Mean curvature reduction in the phase 3 trials in the treatment arm was 34% (17 degrees) vs. 18.2% (9.3 degrees) for placebo. Further experience will help determine which patients may benefit most from CCH, which may depend on direction of curve, size of plaque, prevalence of calcification, and duration of disease. The volume of patients seeking treatment for PD may increase over the coming years as public awareness increases with the advent of use of this drug.
- Combination therapy, also known as a “three-armed approach” using daily pentoxifylline and L-arginine, biweekly verapamil injections, and daily traction likely provides the best opportunity for deformity improvement by creating a synergy between the chemical effects of the oral and/or injectable agents with the mechanical effects of external forces on the penis.

standard of care (Kendirci and Hellstrom, 2004; Gur et al, 2011) because there are multiple factors to consider, including severity of curvature, direction of curvature, presence of a hinge effect, erection quality, and patient goals. An algorithm for surgical decision making is presented in Figure 31-10 (Levine and Larsen, 2013).

Preoperative consent is critical because patients with PD are distressed and frequently emotionally devastated. It has been reported that men who have undergone treatment for PD are often not satisfied with their results because of their expectation for recovery of their pre-Peyronie penile appearance (Jones, 1997). It is therefore important to have a frank discussion with the patient so that he understands the limitations of the operation, as well as to set appropriate expectations regarding outcomes to optimize patient satisfaction (Jordan and McCammon, 2007; Ralph et al, 2010). The patient should understand that there is a possibility of persistent or recurrent curvature, reduction of penile erect length, diminished rigidity, and decreased sexual sensation (Box 31-5). Persistent or recurrent curvature is unusual but has been shown in up to 16% of men, the great majority of whom do not require another operation (Taylor and Levine, 2007; Ralph et al, 2010). The patient should understand that the goal is to make the penis “functionally straight,” which expert opinion defines as a residual deformity of 20 degrees or less (Ralph et al, 2010; Levine and Burnett, 2013). The European Association of Urology (EAU) guidelines committee on PD defines successful curvature correction as 15 degrees or less of residual curvature (Hatzimouratidis et al, 2012). Change in penile erect length is more likely with plication than with grafting, although all surgical correction procedures have been associated with some length loss. This is extremely important for the patient to understand preoperatively because 70% to 80% of patients initially have loss of length as a result of the fibrotic disease process (Pryor and Ralph, 2002; Jordan and McCammon, 2007; Ralph et al, 2010). Thus, further loss of length can be a major concern. Having stretched flaccid penile length documented preoperatively permits comparison with postoperative length. Diminished rigidity has long been reported after surgery, and studies have demonstrated that up to 50% of men may have some degree of postoperative reduction in rigidity, which may respond to a PDE5 inhibitor. Rigidity will not likely be

TABLE 31-1 Oral Agents for Peyronie Disease (PD)

TREATMENT	MECHANISM OF ACTION	STUDY OUTCOMES	ADVERSE EFFECTS
Potaba	Decreases serotonin levels by increasing monoamine oxidase activity, resulting in enhancement of the antifibrotic properties of tissues	Decreased plaque size, no decrease in curvature	Anorexia, nausea, fever, skin rash, hypoglycemia, acute hepatitis
Vitamin E	Antioxidant, limits oxidative stress of reactive oxygen species shown to be increased in PD	No benefit	Possible cerebrovascular events, nausea, vomiting, diarrhea, headache, dizziness
Tamoxifen	Induces the production of TGF- β in an estrogen receptor-independent fashion, theoretically causing macrophage deactivation and T-lymphocyte suppression, thus preventing further fibrogenesis	No benefit	Alopecia, retinopathy, thromboembolism, pancytopenia
Colchicine	Microtubule depolymerization; inhibits cell mitosis, mobility, adhesion of leukocytes, and transcellular movement of collagen and stimulates the production of collagenase	No benefit	Myelosuppression, diarrhea, nausea, vomiting
Carnitine	Increases mitochondrial respiration; decreases free radical formation	No benefit	Seizures, diarrhea, nausea, stomach cramps, vomiting
Pentoxifylline	Blocks the TGF- β 1-mediated pathway of inflammation; prevents deposition of collagen type I; is a nonspecific phosphodiesterase inhibitor; decreases platelet-activating factor	Decreased curvature in 33% of patients, mean 23 degrees	Nausea, vomiting, dyspepsia, malaise, flushing, dizziness, and headache

TGF, transforming growth factor.

TABLE 31-2 Intralesional Agents for Peyronie Disease (PD)

TREATMENT	MECHANISM OF ACTION	STUDY OUTCOMES	ADVERSE EFFECTS
Verapamil	Calcium channel blocker inhibits fibroblast proliferation, extracellular matrix protein synthesis and secretion; increases collagenase activity.	Reduction of curvature and plaque-associated penile narrowing, improvement in quality of erection	Nausea, lightheadedness, penile pain, ecchymoses
Nicardipine	DHP type of calcium channel blocker. In vitro study demonstrated that it is more effective than a non-DHP type, verapamil, in reducing glycosaminoglycan biosynthesis and production of extracellular matrix, such as collagen.	Reduction of pain, improvement in IIEF-5 score, and reduction of plaque size; no benefit in curvature	No severe side effects, such as hypotension or other cardiovascular events
Interferon alfa-2b	Decreases plaque fibroblast proliferation in dose-dependent fashion, decreases the production of extracellular collagen, and increases the production of collagenase.	Decrease in curvature of 27% (13.5 degrees) vs. 9% (4.5 degrees) in the placebo group	Sinusitis, flulike symptoms (fever, chills, and arthralgia), and minor penile swelling with ecchymosis
Clostridial collagenase	Selectively degrades collagen types I and III in connective tissues despite the presence of TIMPs, which have been shown to be elevated in PD and to increase apoptosis of fibroblasts.	Decrease in penile curvature by 34%, mean decrease of 17 degrees vs. 18%, mean decrease 9.3 degrees in placebo; PD symptom bothersomeness score significantly improved vs. placebo	Contusions, ecchymoses, corporeal rupture

DHP, dihydropyridine; IIEF, International Index of Erectile Function; TIMPs, tissue inhibitors of metalloproteinases.

TABLE 31-3 External Force Application for Peyronie Disease

TREATMENT	MECHANISM OF ACTION	STUDY OUTCOMES	ADVERSE EFFECTS
Electromotive drug administration	Bypasses hepatic metabolism, increases concentration of drug to target tissues compared with topical application alone	Verapamil alone: no benefit Verapamil + dexamethasone: decreases in plaque volume as well as penile curvature from 43 degrees to 21 degrees	Temporary erythema at the electrode site
Extracorporeal shockwave therapy	Direct damage to the penile plaque; increases vascularity of the targeted area inducing an inflammatory reaction, resulting in lysis of the plaque and removal by macrophages	Improvements in pain, IIEF-5 score, and mean QoL score; no curvature reduction	Local petechiae and ecchymoses
Penile traction	Decreases α -smooth muscle actin, increases matrix metalloproteinases involved in collagen degradation	Length increased 0.5-2.0 cm; girth increased 0.5-1.0 cm; curvature mean decrease of 20 degrees; pain decreased; softening or shrinking of plaque; overall satisfaction 85%	Erythema in the balanopreputial sulcus, discomfort
Vacuum therapy	Unknown; mechanical effects similar to traction have been suggested	Reduction in the angle of curvature by 5-25 degrees in 21 of 31 patients	Development of PD, urethral bleeding, skin necrosis, and penile ecchymosis
Radiation therapy	Anti-inflammatory effects via functional modulation of the adhesion of white blood cells to activated endothelial cells and modulation of the induction of nitric oxide synthase in activated macrophages	No clinical benefit	Possible malignant change, increased risk of ED in elderly

ED, erectile dysfunction; IIEF, International Index of Erectile Function; QoL, quality of life.

BOX 31-4 Indications for Surgery

- Stable deformity for at least 6 months from onset of symptoms
- Inability to engage in satisfactory penetrative sexual intercourse because of deformity and/or inadequate rigidity
- Failed conservative treatment
- Desire for most rapid and reliable result

BOX 31-5 Preoperative Consent

Set expectations regarding outcome.

- Persistent or recurrent curvature: The goal is “functionally straight” (curvature <20 degrees)
- Change in length: The result is more likely shorter with plication than with grafting.
- Diminished rigidity
 - $\geq 5\%$ in all studies—grafting more than plication
 - $\geq 30\%$ if suboptimal preoperative rigidity—dependent on preoperative erectile quality
- Decreased sexual sensation
 - Typically resolves in 1 to 6 months
 - Rarely compromises orgasm or ejaculation

improved by penile straightening, and therefore in patients who already have significant ED that does not respond to oral medication, placement of a penile prosthesis should be offered (Taylor and Levine, 2007; Ralph et al, 2010). Men who are considering penile straightening procedures without a penile prosthesis should be carefully evaluated for the quality of their preoperative erections, which does appear to be the most reliable predictor of postoperative ED (Flores et al, 2011; Taylor et al, 2012). In some men with PD and ED the correction of the penile geometry resulted in improved rigidity (Pescatori et al, 2003). Regardless, it is of critical importance that the patient understand that any operation done on the penis to correct PD may result in diminished rigidity, and that this may subsequently be treated successfully with oral PDE5 inhibitors, injection therapy, or a vacuum device; and those in whom these approaches fail can have a penile prosthesis implanted with little to no additional difficulty (Kendirci and Hellstrom, 2004; Levine et al, 2010; Chung et al, 2012c). Decreased sexual sensation has been examined and reported on infrequently, but it does appear that around 20% of men will describe some reduction in penile sensitivity, rarely interfering with orgasm or ejaculation. During the acute postoperative period there can be hyperesthesia or hypoesthesia, which tends to resolve and stabilize within 6 to 12 months postoperatively (Taylor and Levine, 2008; Ralph et al, 2010). The primary determinants for the choice of surgical approach are based on two factors, including quality of the preoperative erection hardness and severity of deformity, including curvature and indentation. In men who have rigidity that is adequate for coital activity with or without pharmacotherapy, tunica plication techniques and plaque incision or partial excision with grafting may be used. Tunica plication techniques are recommended for those who have a simple curvature of less than 70 degrees, those with absence of an hourglass or hinge effect, and those in whom the anticipated loss of length would be less than 20% of the total erect length (Levine and Lenting, 1997; Ralph and Minhas, 2004; Mulhall et al, 2005). The estimated penile length loss can be determined during preoperative testing while the penis is erect by measuring the difference in length between the long and short sides of the penis. Grafting procedures are recommended for those with more complex curves of greater than 60 to 70 degrees and/or a destabilizing hourglass resulting in a hinge effect. This hinge effect results in

a buckling or unstable penis, which makes penetrative sex difficult. These men must have strong, sexually induced rigidity to reduce the likelihood of postoperative ED (Flores et al, 2011; Taylor et al, 2012) (Table 31-4). For the man who has PD and ED that is refractory to medical therapy, published algorithms have indicated that penile prosthesis placement is the procedure of choice (Levine and Dimitriou, 2000; Mulhall et al, 2005; Ralph et al, 2010; Levine and Burnett, 2013). This procedure allows for correction of the deformity while also addressing the ED. If curvature is not satisfactorily corrected with the prosthesis inflated during surgery, additional straightening maneuvers may be performed. We recommend manual modeling as the first step as initially reported by Wilson and Delk (1994). If there is residual curvature in excess of 30 degrees after modeling, then a relaxing incision in the tunica albuginea overlying the area of maximum curvature can be made. It is recommended that if the incisional defect is greater than 2 cm, a biograft (i.e., pericardium or small intestine submucosa) should be placed over the defect to prevent cicatrix contracture of the incision or herniation of the prosthesis (Levine and Dimitriou, 2000; Ralph et al, 2010). Plication techniques have been recommended to be performed before placement of the prosthesis to correct curvature in lieu of manual modeling (Rahman et al, 2004; Dugi and Morey, 2010). In this circumstance, if the curvature is dorsal, the erectile deformity can be defined with injection of a vasoactive drug and infusion of saline, then sutures are placed in a Lambert fashion to cause ventral shortening and correction of the curve.

Tunical Shortening Procedures

Penile plication aims to shorten the longer (or convex) side of the tunica albuginea to match the length to the shorter side (Syed et al, 2003; Ralph, 2006). Advantages to these approaches include shorter surgical time, good cosmetic outcomes, minimal effect on rigidity, simple and safe surgery, and effective straightening (Hudak et al, 2013; Hatzimouratidis et al, 2012). Disadvantages include shortening and failure to correct an hourglass or hinge. A study of failures with the Nesbit procedure identified three factors associated with an unsatisfactory outcome, including impaired preoperative erectile function, penile shortening of greater than 2 cm, and penile deformity greater than 30 degrees (Andrews et al, 2001). Multiple surgical plication techniques have been offered for PD, beginning with the Nesbit procedure (Nesbit, 1965) (Fig. 31-11). This technique uses excision of an elliptical segment of the tunica on the contralateral side of the curvature. In the setting of a ventral curvature, once Buck's fascia has been elevated, small wedges of the dorsal tunica albuginea are excised and then the defect is closed, typically with permanent suture. Multiple variations on this approach have evolved, including the Yachia procedure, which uses the Heineke-Mikulicz technique (Yachia, 1990; Yachia, 1993). In the setting of a dorsal curvature, a short (0.5 to 1.5 cm), full-thickness vertical incision is made on the ventral shaft tunic, opposite the area of maximum curvature, which is then closed transversely to shorten the ventral aspect and correct the curvature (Fig. 31-12). This approach must be used carefully so that the length of the incision is not too long, such that transverse closure could result in further narrowing of the shaft, possibly resulting in an unstable erection. Several authors have suggested that this approach has a lower risk of perceived penile shortening (Klevmark et al, 1994; Nooter et al, 1994; Sulaiman and Gingell, 1994; Kümmerling and Schubert, 1995; Poulson and Kikeby, 1995; Ralph et al, 1995; Savoca et al, 2000; Savoca et al, 2004).

Imbrication procedures are used to avoid making a full-thickness tunical incision and fold the tunica to correct curvature. The techniques of tunical plication without incision were introduced in 1985 by Essed and Schroeder, who used nonabsorbable sutures placed in a figure-of-eight fashion to enable the knots to be buried (Essed and Schroeder, 1985). Two years later, Ebbehøj and Metz (1987) described their plication technique using multiple rows of sutures to shorten the longer side for congenital curvature (Ebbehøj and Metz, 1987). The 16-dot procedure has become a popular variation

ED, erectile dysfunction; NR, not reported.

Figure 31-11. A, The Nesbit procedure employs a transverse elliptical incision of the tunica albuginea. B, This is done contralateral to the area of greatest curvature. C, The defect is closed transversely with permanent suture with or without the addition of absorbable suture.

Figure 31-12. A, The Yachia procedure employs a full-thickness vertical incision (B) in the tunica albuginea contralateral to the area of greatest curvature and is closed transversely (C) without removal of tunica albuginea.

Figure 31-13. The dot procedure employs no incision. The tunica albuginea is pliated with permanent suture using an extended Lambert-type suture placement following four dots per plication. A, Suture placement for dorsal curve. B, Suture placement for ventral curve.

of tunical shortening in which there is no incision into the tunic but the tunica albuginea is pliated with permanent suture using an extended Lambert-type suture placement technique (Gholami and Lue, 2002; Brant et al, 2007; Rolle et al, 2005) (Fig. 31-13). Another plication variation is the Levine modification of the Duckett-Baskin tunica albuginea plication (TAP), which was originally used for children with congenital curvature. Here, a partial-thickness incision is made transversely on the contralateral side to the point of maximum curvature (Baskin and Duckett, 1994; Levine, 2006). A pair of transverse parallel incisions 1 to 1.5 cm in length are made through the longitudinal fibers but do not violate the inner circular fibers of the tunic. As a result, the underlying cavernosal tissue is not disturbed, which is thought to reduce the likelihood of postoperative ED. These incisions are separated by 0.5 to 1.0 cm depending on the desired amount of shortening. The longitudinal fibers between the two transverse incisions are excised so as to reduce the bulk of the plication. This procedure is now done with a single central permanent suture (2-0 Tevdek suture, Teleflex Medical, Research Triangle Park, NC, or TiCron suture, Medline, Mundelein, IL) placed in an inverting vertical mattress fashion to bury the knot and then supported with absorbable suture (3-0 polydioxanone [PDS], Ethicon, Somerville, NJ) placed in a Lambert fashion to reduce the palpable nature of the plication and knots (Fig. 31-14).

The key is that all plication procedures shorten the long side of the penis and therefore can result in loss of length on that aspect of the penis. Studies have examined the loss of penile length after use of the TAP technique. The expected factors that predicted loss of length included the direction of curvature and the degree of curvature (Greenfield et al, 2006). Greenfield and colleagues (2006) found that men who had a ventral curvature of

greater than 60 degrees tended to have the greatest potential loss of penile length. Preoperative penile length and degree and direction of curvature deformity appear to correlate with postoperative satisfaction (Mulhall et al, 2005; Greenfield et al, 2006).

The drawbacks of any tunica plication procedure for PD are that it does not correct shortening and it potentially may enhance loss of penile shaft length. It does not address hinge or hourglass effect and may exacerbate it, resulting in an unstable penis. The plaque is also left in situ. Penile narrowing or indentation has been reported in up to 17% with these techniques. In addition, there can be pain associated with the knots and suture granulomas (Tornehl and Carson, 2004; Taylor and Levine, 2008; Ralph et al, 2010). Surgical straightening with plication procedures can be expected in 79% to 100% of patients, with a reported satisfaction rate of 65% to 100% (Van der Horst et al, 2004; Ding et al, 2010; Larsen and Levine, 2013). Recurrence of penile curvature deformity (greater than 30 degrees) has been reported in up to 12% in a limited number of long-term studies (Taylor et al, 2008; Levine and Burnett, 2013). The reported risk of new ED ranges from 0% to 38%, and diminished sensation has been reported in 4% to 21% with follow-up of up to 89 months. Other, less common complications include hematoma in up to 9% of patients, urethral injury in less than 2%, and phimosis in up to 5% (Tornehl and Carson, 2004; Kadioglu et al, 2011b; Larsen and Levine, 2013). The most recent International Consultation on Sexual Medicine (ICSM) published recommendations regarding plication procedures in 2010 and reported that there was “no evidence that one surgical approach provides better outcomes over another, but curvature correction can be expected with less risk of new ED” when compared with grafting procedures (Ralph et al, 2010) (see

Figure 31-14. The tunica albuginea plication (TAP) procedure (A) employs a pair of transverse parallel incisions (B) separated by 0.5 to 1.0 cm. The incision is made through the longitudinal fibers but does not violate the inner circular fibers of the tunic. C, The longitudinal fibers between the two transverse incisions are removed to reduce the bulk of the plication. D, The defect is then brought together transversely.

ED, erectile dysfunction; NR, not reported.

Table 31-5 for a summary of outcomes of tunical shortening procedures).

Tunical Lengthening Procedures (Plaque Incision or Partial Excision and Grafting)

Indications for plaque incision and grafting (PIG) or partial plaque excision and grafting (PEG) for surgical correction of PD includes greater complexity of disease with several (or

all) of the following: curvature greater than 60 to 70 degrees, shaft narrowing, hinging, and extensive plaque calcification (Levine and Lenting, 1997; Kendirci and Hellstrom, 2004; Ralph et al, 2010; Kadioglu et al, 2011b; Levine and Burnett, 2013). Most important, for the patient to be a candidate for incision or PEG, he must have strong preoperative erections (Taylor et al, 2012). This can be determined during the patient interview, when he is asked directly, "If your penis was straight, would the quality of rigidity that you currently have allow penetrative sex?" Should the patient hesitate or note suboptimal-quality erections,

a grafting procedure should not be performed unless the patient fully understands the risk of more advanced postoperative ED and the possible need for subsequent prosthesis placement to obtain optimal rigidity. Some men simply reject the idea that they need a prosthesis as a first-line surgical treatment. Others who might be considered candidates for tunica plication reject this approach because of fear of penile length loss. These men may be offered a grafting repair with the understanding that a penile prosthesis can be placed with minimal added difficulty at a later time. The advantage of performing the grafting procedure is that it would likely correct curvature and reestablish more normal shaft caliber while increasing the likelihood of some length recovery in the range of 0.5 to 3.0 cm.

Other factors have been reported in the literature as possible predictors of postoperative ED, including age older than 55 years, evidence of corporeal veno-occlusive dysfunction on duplex ultrasound analysis with a resistance index of less than 0.80, large tunica defect and graft size, ventral curvature, and curvature greater than 60 degrees (Leungwattanakij et al, 2001; Levine et al, 2005; Alphs et al, 2010; Flores et al, 2011). These predictors have been suggested as a result of single-center studies, with a limited number of patients in each cohort. Larger-scale studies indicate that the most critical criterion for any grafting procedure is the quality of preoperative erections (Flores et al, 2011; Taylor et al, 2012). In fact, Jordan and Angermeier found that there was a linear association between preoperative and postoperative ED (Jordan and Angermeier, 1993). Expert opinion has been consistent that patients with ventral deformity do not do well with grafting procedures. In fact, Hellstrom's analysis of the relationship of penile deformity to the vascular status of PD patients showed that men with ventral curvature had the greatest likelihood of having cavernous veno-occlusive dysfunction (Lowsley and Boyce 1950; Jordan and Angermeier, 1993).

Surgical grafting techniques include PIG and PEG. Historically, total excision of the plaque was practiced to "cut out the disease," resulting in onlays of large grafts with an unacceptably high rate of ED (Kendirci and Hellstrom, 2004; Kadioglu et al, 2006). Therefore, plaque incision was introduced in which a modified-H or double-Y incision is made in the area of maximum curvature (Gelbard, 1995). This allows the tunic to be expanded in this area, thereby correcting the curvature and shaft caliber but minimizing the underlying exposure of the cavernous tissue and thereby reducing the potential fibrosis of the cavernosal tissue and/or interrupting the delicate veno-occlusive mechanism, which has been considered the most likely contributor to postoperative ED with these grafting procedures (Dalton et al, 1991; Hatzimouratidis et al, 2012). Using the modified-H incision allows the correction of the curvature and shaft caliber. Gelbard (1995) has suggested that using multiple incisions and filling them with grafts would result in a smoother correction of curvature and potentially less injury to the underlying cavernosal tissue (Gelbard, 1995).

We favor PEG in which the area of maximum deformity is excised, particularly if it is associated with severe indentation. An increasing number of patients with severe deformity have indentation that if not addressed may result in a straightened penis but with residual narrowing causing instability. The corners of the defect are darted in a radial fashion to enhance correction of the narrowing in that area (Levine, 2011). Geometric principles have been applied to the grafting technique so as to obtain a properly sized graft with excellent correction of deformity (Egydio et al, 2004). This approach has been considered unnecessarily complex, and there have been reports of a higher rate of postoperative ED when this technique has been used (Flores et al, 2011). It appears intuitive that to reduce the risk of postoperative ED, the key is to limit the trauma to the underlying cavernosal tissue to maintain the veno-occlusive relationship between the cavernosal tissue and the overlying tunica graft.

Graft Materials

The ideal graft should approximate the strength and elastic characteristics of normal tunica albuginea; should have minimal

morbidity and tissue reaction; should be readily available, not too thick, pliable, easy to size and suture, inexpensive, and resistant to infection; and should preserve erectile capacity (Gur et al, 2011; Kadioglu et al, 2007). Multiple autologous grafts have been used historically, including fat, dermis, tunica vaginalis, dura mater, temporalis fascia, saphenous vein, crura or albuginea, and buccal mucosa (Lowsley and Boyce, 1950; Devine and Horton, 1974; Das, 1980; Lue and El-Sakka, 1998; Teloken et al, 2000; Sampaio et al, 2002; Leungwattanakij et al, 2003; Kargi et al, 2004; Shiosh-vili et al, 2005; Kadioglu et al, 2007). These have fallen out of favor because of a need for extended surgery to harvest the graft as well as a second surgical site, which possesses its own potential complications of healing, scarring, and possible lymphedema. Crural and buccal grafts are compromised by the inability to get enough graft material for large defects (Hatzichristou and Hatzimouratidis, 2002; Schwarzer et al, 2003; Shiosh-vili et al, 2005). Synthetic polyethylene terephthalate (PETE, Dacron) and polytetrafluoroethylene (PTFE, Teflon) grafts have been used historically and are not recommended now because of the potential risk of infection, localized inflammatory response, and fibrosis (Devine et al, 1997; Brannigan et al, 1998). Finally, "off-the-shelf" allografts and xenografts have emerged, including processed pericardium from a bovine or human source, porcine intestinal submucosa, and porcine skin. The two most common grafts currently used are Tutoplast (Coloplast US, Minneapolis, MN), processed human and bovine pericardium, and porcine small intestinal submucosa (SIS) grafts (Surgisis ES, Cook Urological, Spencer, IN) (Hellstrom, 1994; Hellstrom and Reddy, 2000; Knoll, 2001; Levine and Estrada, 2003). These packaged processed grafts are being used with increased frequency because of their ease of use and reduction in operating times. The pericardial grafts are thin, are strong, do not contract, and have no reports of infection or rejection. Chun and associates (2001) performed a comparison of dermal and non-Tutoplast processed human cadaveric pericardial grafts in the modified Horton-Devine procedure. Overall, 92% of patients were able to achieve successful coitus with or without assistance. These researchers reported a 33% overall recurrence rate, with 26% of patients who received dermal grafts and 44% of patients who received pericardial grafts experiencing recurrence. However, this study did not report on the severity of recurrence, and all these patients were able to achieve erections suitable for coitus. Satisfaction rates were similar, and those who underwent pericardial grafting had shorter operative times as well as decreased morbidity associated with the absence of a graft donor site (Chun et al, 2001). The SIS grafts have similar advantages to pericardium, except there have been reports of graft contraction, particularly with one-ply grafts, with associated recurrent curvature in the 37% to 75% range (Santucci et al, 2005; John et al, 2006; Breyer et al, 2007; Kovac and Brock, 2007; Taylor and Levine, 2008). Other reported postoperative complications with SIS grafts include subgraft hematoma in 26% and an infection rate of 5% (Breyer et al, 2007).

Tissue-engineered graft materials have been considered more recently and potentially offer the advantage of having a graft seeded with cellular material, which may enhance the take of the graft and potentially reduce local tissue fibrosis with diminished postoperative ED. Adipose tissue-derived stem cell-seeded SIS, human acellular matrix tunica albuginea grafts, and autologous tissue-engineered endothelialized tunica albuginea grafts have been investigated for incision and excision procedures (Schultheiss et al, 2004; da Silva et al, 2011; Imbeault et al, 2011; Ferretti et al, 2012; Ma et al, 2012). Imbeault and associates (2011) demonstrated in vitro creation of artificial tunica albuginea using human dermal fibroblast and human endothelial cells. They concluded that this tissue-engineered endothelialized tubular graft was structurally similar to normal tunica with a high burst pressure and adequate mechanical resistance. Furthermore, the autologous property of this model could represent an advantage compared with other available grafts (Imbeault et al, 2011). Such studies may help elucidate future medical treatments for PD using tissue-engineered grafts for the reconstruction of the tunica albuginea. The biomechanical properties, compatibility with the tunica albuginea, and effective neovascularization of the

tissue-engineered grafts need to be investigated further before such basic research can be applied in practice.

Grafting Surgical Technique

Once the patient has achieved satisfactory general anesthesia, it is advised that the patient receive a dose of intravenous antibiotics and that the deep venous thrombosis protection apparatus be applied. The dorsal SPL should be measured. An artificial erection is then created by injecting a vasoactive drug (papaverine, Trimix, prostaglandin E₁) via a 21-gauge butterfly needle placed through the glans into the corpus cavernosum. Saline can be infused to create a full rigid erection, which allows visualization and measurement of the deformity, including curvature and areas of indentation with or without hinge effect. The preferred approach for grafting procedures is a circumcising incision made approximately 1.5 to 2 cm proximal to the corona, or through a previous circumcision site. The penis is degloved down to the Buck fascia, at which point hemostasis is obtained with bipolar cautery. It is advisable for the surgeon to use loupe magnification to reduce the likelihood of injury to neurovascular structures. With the shaft exposed, the erection can again be re-created, demonstrating the area of maximum deformity. In the circumstance of a dorsal or dorsal-lateral curvature, the Buck fascia, with the enclosed neurovascular bundle, is elevated by making a pair of parallel incisions just lateral to the urethral ridge, through the Buck fascia to the tunica albuginea. The Buck fascia is carefully elevated off the tunic. Typically this can be done with delicate, sharp dissection, but occasionally, if there is significant adhesion between the Buck fascia and the tunic, bipolar cautery can be used to elevate this with minimal risk of permanent nerve injury. Once the Buck fascia is elevated off the area of maximum deformity, a full erection is re-created. The area of maximum deformity is marked for incision or partial plaque excision. This allows excision and expansion of areas of severe indentation. It should be noted that even with a pure lateral curvature, the tunic to be excised must traverse through the dorsal septum, because this is the anchor point of the scar and if it is not taken, substantial residual curvature will likely remain (Jordan, 2007). When extensive calcification extends beyond the area of partial plaque excision, the calcified component can be removed, leaving the outer lamina intact because the calcification involves the inner circular fibers. Once the rectangular defect is established, the corners are darted in a radial fashion so as to help to recover normal shaft caliber in the area of indentation. We have simplified the geometric principle technique by ensuring that the lateral sides of the defect are of equal length (Egydio et al, 2004; Levine, 2011). In doing this, we create a uniform-sized square or rectangle, which virtually always allows satisfactory correction of lateral and dorsal curvature. Often the proximal transverse length will be longer than the distal transverse length because of distal tapering of the shaft. The penis can now be measured on stretch again; typically there will be increased dorsal length from 0.5 to 3.0 cm. Stay sutures of 4-0 PDS (Ethicon, Somerville, NJ) are placed in the four corners of the defect and at the midpoint transversely, distally, and proximally. With these stay sutures on stretch, the defect can be measured longitudinally and transversely. Our preference is to use a Tutoplast processed pericardial graft (Coloplast, Minneapolis, MN), because there is usually little graft contraction. The graft should be sized no more than 10% larger than the measured defect on stretch. Porcine SIS grafts (Cook Urological, Spencer, IN) need to be oversized by 25%. Once the graft has been cut to size, it is secured in place with the previously placed stay sutures; then, with 4-0 PDS placed in a running fashion, the graft is secured to the defect. If a large defect is created, it may be advisable to place several interrupted 4-0 PDS sutures in the area of the septum to reduce the volume of blood that can accumulate under the graft. An artificial erection is again reestablished; if there is significant residual curvature, this can be addressed with tunica plication. We have found that this is necessary in up to 25% of patients. In patients who have a more prolonged curve or in those who have substantial indentation in one area as well as a more distal curvature, the grafting should be performed in the area of indentation, and plication is used to address any residual

dorsal or lateral curve once grafting has been completed. In this circumstance a single graft can be used, which has not been shown to have a higher rate of postoperative ED than when multiple grafts are used but does have the advantage of shorter operative time. Once satisfactory deformity correction has been accomplished, the Buck fascia is reapproximated with running 4-0 chromic, and the shaft skin is reapproximated to subcoronal skin with interrupted 4-0 chromic in a horizontal mattress fashion. Of note, for those patients who are uncircumcised and do not have any evidence of phimosis, a circumcision is not necessary (Garaffa et al, 2010); but if there is any question of excessive redundant foreskin and/or phimosis, then circumcision should be performed to reduce the likelihood of postoperative paraphimosis (Garaffa et al, 2010). The penis is dressed with Xeroform gauze (3M, St. Paul, MN) placed over the circumcising incision, and then a Coban wrap (3M, St. Paul, MN) is placed distal to proximal, providing gentle compression. Typically the dressing is left in place for 3 days and then removed, at which point the patient may shower. Submersion of the wound is not advised because this may encourage wound separation.

Postoperative Management

The postoperative rehabilitation period is critical to reduce the risk of postoperative ED and length loss as well as to optimize straight healing. We find it useful to liken the importance of postoperative rehabilitation after penile surgery to the importance of the rehabilitation needed for successful orthopedic joint replacement. Typically a patient is seen 2 weeks after surgery, at which point massage and stretch therapy are initiated (Horton et al, 1987). The patient is instructed to grasp the penis by the glans and gently stretch it away from the body and then with his other hand to massage the shaft of the penis for 5 minutes twice per day for 2 to 4 weeks. The massage and stretch can be performed by the patient's partner for the second 2 weeks if possible. This will reinitiate the sexual experience for the couple and hopefully diminish the fear of reinjuring the penis, for which the partner may feel responsible. Investigators have recommended the use of nocturnal PDE5 inhibitors to enhance postoperative vasodilation, which may help support graft take, reduce cicatrix contraction, and theoretically preserve cavernosal tissue, thereby reducing postoperative ED (Levine et al, 2005). Finally, external penile traction devices have been encouraged and have been recently shown to reduce length loss postoperatively and can even enhance length gain after both grafting and plication procedures (Levine et al, 2013). In a recent report, SPL in patients who used postoperative traction therapy was shown to increase after plication and PEG procedures by +0.85 cm and +1.48 cm, respectively, versus length changes of -0.53 cm and +0.24 cm in the plication and PEG groups in which postoperative traction was not used. In fact 50% of the plication and 89% of the PEG patients using postoperative traction had measured length gain. The reported average daily use was 2.5 hours for 4.5 days per week for an average duration of 3.8 months. There was no patient reported with postoperative length loss among those who used postoperative traction therapy, and although not statistically significant, there was a trend of higher satisfaction for erect length in the groups in which postoperative traction was used. Traction is recommended to be used for 3 or more hours per day, beginning 3 to 4 weeks after surgery, once the wound can tolerate the pressures of the stretching device for 3 months (Rybak et al, 2012).

In a review of the published reports on grafting for PD over the past 12 years, satisfactory straightening was found in 74% to 100% of patients, but postoperative ED, which does not have a uniform definition in the literature and may include reduced rigidity, compared with preoperative rigidity, to complete loss of rigidity, has been reported in 5% to 54% of patients. Diminished sensation after grafting has been reported in a few series with a follow-up of less than 5 years (Taylor and Levine, 2008). In the few single-center surgical outcome reviews with 5 or more years of follow-up, ED has been reported in up to 24%, with recurrent or persistent curvature in the 8% to 12% range (Montorsi et al, 2004; Kalsi et al, 2005; Chung et al, 2011a; Usta et al, 2003). See Table 31-4 for a summary

of the outcomes for penile straightening with plaque incision or excision and grafting.

Penile Prosthesis for Men with Peyronie Disease

Indications

In men with PD and concurrent ED refractory to PDE5 inhibitors, penile prosthesis placement is the procedure of choice (Levine and Lenting, 1997; Levine and Dimitriou, 2000; Kendirci and Hellstrom, 2004; Ralph and Minhas, 2004; Mulhall et al, 2005). Additional straightening maneuvers may be necessary, including manual modeling and incising of the tunica albuginea with or without grafting. Recently, transcorporeal approaches have been used before modeling or relaxing incisions; the plaque is incised or stretched from within the corporeal body (Shaer, 2011; Perito and Wilson, 2013).

Techniques for Straightening When Placing a Penile Prosthesis for Peyronie Disease

An inflatable penile prosthesis (IPP) appears to be the preferred surgical implant, as the pressure within the cylinders allows for superior correction of curvature with manual modeling, as well as improved girth enhancement. Malleable prostheses, when used for PD historically, were associated with narrow, cold, and less than natural erections (Montorsi et al, 1993; Ghanem et al, 1998; Marzi et al, 1997).

Manual modeling via the penoscrotal approach is recommended with a high-pressure inflatable cylinder, but all available three-piece and two-piece devices have been used successfully to correct deformity (Wilson and Delk, 1994; Montague et al, 1996; Montorsi et al, 1996; Levine et al, 2001; Chung et al, 2012c). Our approach is to place the prosthesis cylinders first, followed by closing of the corporotomies. With use of a surrogate reservoir attached to the pump tubing, the prosthesis can be filled to full rigidity, which will allow visualization of the deformity. To protect the pump from the high pressures that may occur during manual modeling, shodded hemostat clamps are applied to the tubing between the pump and the cylinders. The penis is then bent in the contralateral direction to the curvature. It is recommended to try to hold the penis in this position for 60 to 90 seconds, but experience has suggested that around 30 seconds may be all that is possible. Once the modeling has been performed, the penis can be reassessed by instilling more fluid, reapplying the hemostats, and then performing the modeling procedure repeatedly until satisfactory curvature correction has been attained. **The modeling technique should be a gradual bending rather than a violent maneuver, because this will reduce the likelihood of inadvertent tearing of the tunic or injury to the overlying neurovascular bundle.** Urethral injuries during performance of this technique as a result of distal extrusion of the prosthetic cylinders at the fossa navicularis have been reported (Wilson and Delk, 1994; Wilson et al, 2001). To reduce the likelihood of this occurring, the bending hand should be placed on the shaft of the penis rather than on the glans, to avoid downward pressure on the tips of the cylinders. The other hand should be grasping the base of the penis with pressure over the corporotomies, which will provide support to this area and reduce the likelihood of disruption of the suture line.

Published reports on the use of modeling have indicated that successful straightening can be expected in 86% to 100% with no higher incidence of device revision; sensory deficit after manual modeling is rare but remains a potential complication that should be discussed with the patient preoperatively (Wilson and Delk, 1994; Montague et al, 1996; Wilson et al, 2001; Levine et al, 2010; Chung et al, 2012c). Although it would appear that for more severe curvature more advanced techniques are necessary, published experience has suggested that manual modeling may be used as first-line therapy for correction of curvature after prosthesis implantation (Levine et al, 2010; Chung et al, 2012c). An alternative to this would be to perform a tunic plication contralateral to the curvature before

placement of the prosthesis to correct the curvature (Rahman et al, 2004; Dugi and Morey, 2010). When there is residual curvature of greater than 30 degrees or residual indentation causing the inflated cylinder to buckle, tunical incision is recommended after elevation of the Buck fascia in that area (Levine and Dimitriou, 2000).

The transverse penoscrotal skin incision will allow access to virtually the entire shaft, except when the curvature is distal and dorsal on the shaft, so degloving the penis is not always necessary. The tunical incision is made with the cylinders deflated, using the cautery to release the tunic with an effort to preserve cavernosal tissue over the implant. When Titan cylinders (Coloplast, Minneapolis, MN) are used, the energy should be less than 30 watts to reduce potential cylinder thermal injury (Hakim et al, 1996). Once the incision has been made, the cylinders are reinflated and further modeling can be performed to optimize deformity correction. Although there is not a clearly accepted approach, grafting is recommended when the defect measures greater than 2 cm in any dimension to reduce cicatrix contracture and cylinder herniation (Levine and Dimitriou, 2000; Carson and Levine, 2014). Historically, synthetic grafts were used, but currently biografts of pericardium or porcine SIS are recommended. Use of locally harvested dermal grafts is not recommended, because there is risk of transferring bacteria to the prosthesis.

There have been limited publications looking at the long-term results with regard to outcomes and satisfaction with inflatable penile prostheses in men with PD and ED. Levine and associates (2010) reported on 90 consecutive men undergoing placement of an IPP, with 4% having satisfactory straightening with prosthesis placement alone, 79% having satisfactory curvature correction with prosthesis and modeling, 4% requiring tunical incision, and 12% having incision and pericardial grafting for correction of curvature. There was no evidence that the additional maneuvers increased the rate of mechanical failure or infection with up to 8 years of follow-up. In the nonvalidated questionnaire used in this study, overall patient satisfaction was 84%, whereas only 73% were satisfied with curvature correction. This may indicate a flaw in the design of the questionnaire, but may also reflect the general disappointment and frustration of patients with PD (Levine et al, 2010). Thus, preoperative counseling and setting appropriate expectations as with any prosthesis placement are critical (Akin-Olugbade et al, 2006). It is recommended that preoperative discussion also be focused on the goal of obtaining "functional straightness," in which a residual curvature of 20 degrees or less in any direction would likely not compromise sexual activity and may correct in time as a result of tissue expansion caused by the cylinders. A comparison of outcomes between the two three-piece inflatable devices in North America found no significant advantage with respect to device reliability, infection, or patient satisfaction (Chung et al, 2012c).

By far the most common postoperative complaint heard from men who have undergone penile prosthesis placement is length loss (Montague, 2007). The first to objectively evaluate penile length change after prosthesis implantation were Wang and associates, who demonstrated decreases of 0.8, 0.75, and 0.74 cm at 6 weeks, 6 months, and 1 year after surgery, respectively (Wang et al, 2009). This is of particular concern in the PD population, who often already have loss of penile length. Any additional length loss as a result of the implant may be distressing to the patient and should be addressed preoperatively. For those men who cannot tolerate any further length loss, a recent small pilot study using traction therapy before penile prosthesis placement in men with PD as well as other disorders causing penile shortening (e.g., prosthesis explants, radical prostatectomy) did demonstrate that after 3 to 4 months of daily traction for an average of 3 hours or more per day, there was no further loss of length after prosthesis placement, and the majority had gained some length (0.5 to 2.0 cm) compared with the pretraction SPL (Levine and Rybak, 2011). Postoperative prolonged cylinder inflation has been recommended to maintain penile length and decrease residual curvature; the device is kept inflated for 10 to 30 minutes daily for 3 months starting 6 weeks after surgery. See Table 31-6 for a summary on the outcomes of penile straightening with penile prosthesis placement.

KEY POINTS: SURGICAL MANAGEMENT

- Surgical correction of PD with or without penile prosthesis placement remains the gold standard to correct deformity and is indicated when deformity or rigidity compromises or prevents penetrative sexual activity.
- Surgical candidates need to undergo a detailed and comprehensive consent process so that the patient will understand the potential limitations of the surgery and will have appropriate personal expectations, thereby improving postoperative satisfaction.
- For the man with satisfactory preoperative rigidity with curvature less than 60 to 70 degrees without significant indentation, some form of tunica plication is indicated. There does not appear to be any one plication technique that has been demonstrated to be superior to others, as no head-to-head comparative trials have been published.
- Men who have more severe, complex deformity but who have strong preoperative erectile function and no evidence of venous insufficiency on duplex ultrasound analysis should be considered candidates for straightening with plaque incision or PEG.
- The complications associated with these operations include incomplete straightening, recurrent curvature, shaft shortening, diminished penile sexual sensation, and ED.
- It appears that the nature of the graft is less likely the determining factor with respect to postoperative ED. On the other hand, optimum outcomes are most likely a result of proper patient selection with respect to preoperative erectile status as well as operative technique.
- For men who have inadequate rigidity and PD, penile prosthesis placement with straightening maneuvers as necessary should be considered first-line surgery.

CONCLUSION

PD is far more common than previously thought and is a growth area in urology, not only for clinical practice but also for basic science research. The mysteries of this wound-healing disorder need to be clarified, and this will likely yield better treatment options as well as potential strategies to prevent progression. It should be recognized that there are acute and stable phases and that surgery should be offered only after the scarring process has been stable for 3 to 6 months. Patients with PD should be counseled that complete

correction of the deformity, including curvature, indentation, and shortening, is not likely and that the goal is to allow the patient to function sexually again. The devastating psychological impact of this disease is important to recognize, and psychological counseling is occasionally indicated and should be offered. For patients in the acute phase, not offering any therapy does little for their emotional and physical distress and may allow progression of deformity. Offering nonsurgical treatment including oral, injection, and/or mechanical therapy may stop progression and possibly improve deformity and sexual function. When surgery is indicated, the goal is to correct the deformity and prevent worsening of ED so that penetrative sexual activity is possible. The patient must understand that recovery of his pre-PD penis is not likely and that surgery carries the risk of incomplete straightening and recurrent curvature, further shaft shortening, change in sexual sensitivity, and, most important, diminished postoperative rigidity. For men with drug-refractory ED and PD, placement of a penile prosthesis with straightening maneuvers is the best approach to address both problems with one operation.

SEXUAL WELLNESS

At a technical consultation on sexual health sponsored by the World Health Organization, sexual wellness was defined as (World Health Organization, 2006):

1. A state of physical, emotional, mental, and social well-being in relation to sexuality
2. Not merely the absence of disease, dysfunction, and/or infirmity
3. An important and integral aspect of human development and maturation
4. A human right

Diminished sexual function is associated with impaired quality of life and well-being (Laumann et al, 1999; Davison et al, 2009). Many urologists underestimate the prevalence of female sexual concerns and do not routinely make the assessment of sexual wellness a part of their practice (Bekker et al, 2009) despite evidence that many women in urologic clinics have sexual issues (Elsamra et al, 2010).

Relatively few women discuss sexual issues with their provider (Lindau et al, 2007). There are myriad reasons for this failure to address the issues; an important example is failure of the physician to broach the subject with the patient (MacLaren, 1995; Sadowsky et al, 2006; Sobocki et al, 2012). Despite a common perception that sexuality is not of importance to older women, studies have indicated that sex remains a concern even for a substantial number of elderly women.

Data referable to this may be found on the Expert Consult website.

A basic understanding of female sexual response is important, as urologic conditions and procedures have the capacity to markedly influence female sexual wellness. The astute urologist will be aware of how sexual function may influence or be influenced by urologic conditions and will address these issues with patients.

FEMALE SEXUAL RESPONSE

The Sexual Response Cycle

William Masters and Virginia Johnson were among the first to report on the physical aspects of sexual response (Masters and Johnson, 1966). According to their observations, sexual response begins with the arousal phase. The arousal phase is characterized by vulvar and clitoral swelling, vaginal lubrication and lengthening, nipple erection, increased genital sensitivity, tachycardia,

tachypnea, and subjective pleasure and excitement (Masters and Johnson, 1966; Basson et al, 2010b). The sexual arousal phase is followed by the plateau phase during which sexual excitement/arousal continues (Masters and Johnson, 1966).

Orgasm may follow a variable period of arousal and sexual stimulation. Orgasm is a “variable, transient peak sensation of intense pleasure, creating an altered state of consciousness usually accompanied by involuntary, rhythmic contraction of the pelvic striated circumvaginal musculature, with concomitant uterine and anal contractions and myotonia, usually with an induction of well-being and contentment” (Masters and Johnson, 1966; Meston et al, 2004).

Female orgasm has a long and controversial history; for centuries there was denial that such an entity even existed in healthy women. Female orgasm (and how it can and should be obtained) continues to be a highly controversial topic (Colson, 2010). Many women climax from direct or indirect stimulation of the clitoris; others may experience orgasm during vaginal penetration with or without stimulation of the clitoris or vulva. Some healthy women do not experience orgasm during vaginal penetration under any circumstances (Masters and Johnson, 1966; Wallen and Lloyd, 2011). Anal stimulation may also play a role in attaining orgasm for a minority of women (Herbenick et al, 2010b).

After orgasm(s) there is a resolution phase as sexual excitement declines back to baseline levels. In women this involves reduction in pelvic blood flow, relaxation of nipple erection, and restoration of heart rate to resting levels. Sexual excitement declines to resting levels; a sense of sexual satiety and lack of desire for additional sexual activity is typical of this phase (Masters and Johnson, 1966).

There is a wide range of normal sexual response in women (Bancroft and Graham, 2011). Some women may not experience orgasm during partnered sex; others may have one or several orgasms before a return to the resting state (Fig. 32-1) (Masters and Johnson, 1966). This heterogeneity in sexual response is not necessarily associated with differing levels of sexual satisfaction.

In the 1970s, Kaplan added the concept of sexual desire to the linear response model. Sexual desire was postulated to precede the development of arousal (Kaplan, 1977). In the early 2000s, Basson stated that a linear response may not be reflective of what women experience during sex. An alternative hypothesis is that intrinsic, active sexual desire is not an essential component of sexual health for all women. Some women may have a reactive desire that occurs in response to sexual initiation by a partner or by other external stimuli. In such women, sexual response may

A study sponsored by the American Association of Retired Persons indicated that 61% of women older than 45 years report that a satisfying sexual life is important to them; almost 40% of women older than 70 years continued to view sex as at least somewhat important in their lives (Fisher et al, 2010). Data from the National Social Life, Health, and Aging study indicated that 62%, 40%, and 17% of women aged 57 to 64, 65 to 74, and 75 to 85 reported having sex in the previous year, respectively. Of these sexually active

persons, more than 50% of all age groups reported sex at least twice a month with coital intercourse occurring on at least 75% of sexual encounters (Waite et al, 2009). The Global Survey of Sexual Attitudes and Beliefs (GSSAB) included more than 13,000 women aged 40 to 80 years from around the world and the survey reported that up to 25% of women aged 70 to 80 years engaged in sexual activity at least once a week; the prevalence of sexual activity did vary a great deal by region (Nicolosi et al, 2005, 2006a, 2006b).

Figure 32-1. This linear sexual response cycle corresponds approximately to the models of [Masters and Johnson \(1966\)](#) and [Kaplan \(1977\)](#). Sexual arousal/excitement increases during sexual activity, reaching a peak with orgasm and eventually declining to baseline. Heterogeneity is present in female sexual response, with some women experiencing a single orgasm during a sexual encounter (orange line). Other women may experience multiple orgasms (red line) or no orgasm (blue line). Each of these patterns may be normal in a given woman.

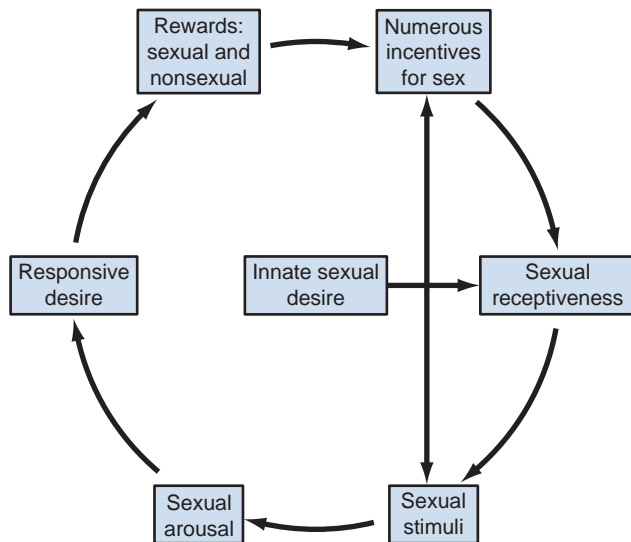

Figure 32-2. This circular sexual response cycle corresponds to the model of [Basson \(2002\)](#). In this model, sexual activity may occur in response to sexual desire or to previous rewards from sexual activity. With positive reward, sexual incentives are increased and sexual activity becomes more likely.

follow a circular model in which sexual activity leads to intra- and interpersonal rewards. This prompts sexual interest and receptiveness to additional sexual experiences ([Fig. 32-2](#)) ([Basson, 2002](#)). The various sexual response models are useful as a means of classification but should not be interpreted as a fixed pattern applicable to every woman and/or in every circumstance ([Bancroft and Graham, 2011](#)).

Studies on models of sexual response are discussed in more detail on the Expert Consult website.

Pelvic Anatomy and Genital Sexual Response

A detailed discussion of pelvic anatomy can be found on the Expert Consult website.

Pelvic anatomy relevant to female sexual response includes the clitoris (glans and crura), labia major and minora, the vulvar vestibule, the vagina, the vestibular bulbs, and the LA muscle ([O'Connell et al, 2008](#)). Engorgement with blood of genital tissues is the

unifying theme of the genital events underlying female sexual arousal ([Suh et al, 2004](#); [Yang et al, 2006](#)). The clitoris (both glans and bulbs) is composed of erectile tissue with large dilated vascular spaces. The vascular spaces of the vagina, labia minora, and urethra are spongy but lack the large sinusoidal spaces of the clitoris; these structures may swell but do not become rigid with arousal ([Yang et al, 2006](#)).

Increased blood flow leads to attenuation of sodium reabsorption and increased oncotic pressure within the vaginal walls ([Munarriz et al, 2002a](#)). Increased oncotic pressure produces a transudative ultrafiltrate that crosses into the vaginal lumen, producing vaginal lubrication ([Fig. 32-4](#) on the Expert Consult website) ([Martin-Alguacil et al, 2006](#)). Aquaporins are critical for the translocation of fluid across the vaginal mucosa. These soluble proteins translocate between the cytoplasm and the cell membrane, permitting efflux of transudate fluid through the vaginal epithelium ([Kim et al, 2009](#)). There are no glandular elements in the vagina itself. There may be some contribution to vaginal lubrication from small cervical glands and to external lubrication from vestibular (also known as Bartholin) glands around the vaginal introitus and/or the urethral Skene glands; these contributions are thought to be relatively minor ([Woodard and Diamond, 2009](#)).

Genital responses are controlled in large part by the autonomic nervous system. Generally, the parasympathetic nervous system enhances sexual response by vasodilation. The sympathetic nervous system opposes sexual responses by vasoconstriction but does play an important role in pelvic contractions with orgasm ([O'Connell et al, 2008](#)). The somatic nervous system plays a role in transmission of sensation and control of motor neurons to the pelvic floor ([Schober and Pfaff, 2007](#)).

Details on nongenital sites relevant to sexual arousal are included on the Expert Consult website.

Molecular Mechanisms

Molecular mechanisms and neuroanatomic information relevant to female sexual response are discussed on the Expert Consult website.

Neurophysiology

Serotonin

Serotonin is an important CNS neurotransmitter and is intimately linked to sexual response. Serotonergic receptors are present in the peripheral nervous system, vasculature, and vestibular glands ([Fetisov et al, 1985](#); [Frohlich and Meston, 2000](#)). Serotonergic agonists induce vascular smooth muscle contraction by action on the 5-HT_{2A} receptor ([Yang and Mehta, 1994](#)). Generally, serotonergic drugs (e.g., selective serotonin reuptake inhibitors [SSRIs]) have an inhibitory effect on sexual desire, arousal, and orgasm ([Balon, 2006](#)).

More information is available on the Expert Consult website.

Dopamine and Oxytocin

Centrally, dopamine and oxytocin have been implicated as pro-organic. Oxytocinergic and dopaminergic agonists increase sexual arousal and initiate sexual solicitation when released in the MPOA ([Caldwell et al, 1989](#); [Graham et al, 2012](#)).

Oxytocin is synthesized in the PVN of the hypothalamus ([Jenkins and Nussey, 1991](#)) and has central and peripheral effects; it appears to mediate pair bonding in some species ([Moscovice and Ziegler, 2012](#)). In humans, oxytocin is released with orgasm and the intensity of sensation appears to correlate with the amount released ([Blaicher et al, 1999](#); [Meston and Frohlich, 2000](#)).

Norepinephrine

Norepinephrine is the predominant sympathetic nervous system neurotransmitter in the peripheral nervous system. Tonic

In a study of 129 female nurses, there was a relatively even split between endorsement of the three aforementioned sexual response cycles (Masters and Johnson, 1966; Kaplan, 1977; Basson, 2002) as most representative of their experience. Interestingly, women at higher risk of sexual dysfunction were significantly more likely to endorse the Basson model (Sand and Fisher, 2007). Giles and McCabe (2009) reported a similar result in a study of 404 women; in this study the linear models were a good fit for the mixed population of women but the circular model was a better fit for women with lower sexual function scores. These authors

determined that many women reported desire preceded arousal, implying that intrinsic sexual desire occurs in women (Giles and McCabe, 2009).

These controversies do not necessarily indicate fundamental defects in the circular model. However, they do imply that secondary gain from sexual activity (e.g., mate guarding, emotional intimacy, etc.) may be important driving factors for sexual activity in women with lower sexual desire, decreased subjective/objective arousal response, and/or difficulty attaining orgasm with partnered sexual activity.

External Genitalia

The external-most portion of the female genital tract is collectively known as the *vulva*. The *mons pubis* is the fleshy area anterior to the pubic bone and superior to the *vaginal introitus*. The mons contains subcutaneous fat and the suspensory ligaments of the *clitoris* (O'Connell et al, 2008).

Labia

The *labia major* are paired, rugated organs located inferior to the mons pubis and extending to the perineum (O'Connell et al, 2008). The labia majora contain abundant adipose tissue with a dual blood supply, making these tissues useful as local flaps for reconstructive surgery in the female pelvis (Given and Acosta, 1990). The labia majora contain numerous sebaceous glands (Salonia et al, 2010), are derived from embryonic ectoderm, and are hence keratinized (Farage and Maibach, 2006). The labia majora are innervated anteriorly by the anterior labial branch of the ilioinguinal nerve and posteriorly by the labial branch of the pudendal nerve (O'Connell et al, 2008).

Between the paired labia majora are the *labia minora*. The labia minora lie on either side of (in descended order) the clitoris, *urethral meatus*, and the *vaginal vestibule* (Puppo, 2013). Inferiorly, the labia minora coalesce to the *posterior fourchette*, the midline skin at the posterior margin of the vaginal introitus.

The labia minora are derived from embryonic endoderm (Farage and Maibach, 2006). The labia minora are thinly or not at all keratinized and consist of vascular tissue in a fibrous stroma (Yang et al, 2006). The labia minora are very sensitive to the presence or absence of sex steroids. There is a wide variation of normal in the appearance of the labia minora (Puppo, 2013). The *vestibular* (also known as Bartholin) glands are paired structures located near the labia minora that produce lubrication during sexual arousal (Levin, 1980).

Labial branches of the external pudendal artery (derived from the femoral artery) supply the labia major and minora. External labial veins drain to the great saphenous vein (O'Connell et al, 2008).

The perineal neurovascular bundles are branches of the pudendal nerve and originate near the takeoff point of the clitoral nerves. The perineal neurovascular bundles are responsible for innervations to the external genitalia (O'Connell et al, 2005) as well as the urethra (O'Connell et al, 2008).

Clitoris

The clitoris is composed of two erectile bodies that extend bilaterally along the ischium lateral to the vagina (Yang et al, 2006). The clitoral bodies contain spongy erectile tissue consisting of lacunar spaces, endothelium, and smooth muscle, which become engorged with blood during arousal (Toesca et al, 1996; Yang et al, 2006; Martin-Alguacil et al, 2008). A fibroelastic sheath called the tunica albuginea covers each corporal body (Yang et al, 2006). The tunica albuginea of the clitoral corpora cavernosa and corpus spongiosum/glans clitoris is relatively thin. This has the effect of reducing the veno-occlusive force during engorgement of the clitoris. Furthermore, the clitoris does not contain a dense network of venous tissue immediately deep to the tunica albuginea (Toesca et al, 1996). The thinness of the tunica albuginea and absence of subtunical venules differs from what is observed in the male phallus. These structural differences account for the less turgid erectile response observed during clitoral erection compared to penile erection.

The majority of clitoral length is located inside the pelvis; the visible glans of the clitoris represents only a small portion of this organ. In the nonerect state the clitoris is partially or completely obscured by the labia minora, which fuse to form the clitoral prepuce (O'Connell et al, 2008). Depending on the size of the clitoris and state of arousal, a portion of the clitoris may protrude beyond the prepuce. In rare cases, fibrosis or atrophy of the superior

margins of the labia may produce entrapment of the glans clitoris, a condition known as clitoral phimosis (Fig. 32-3) (Goldstein and Burrows, 2007).

The glans clitoris is attached to the symphysis pubis by the suspensory ligament (Rees et al, 2000). The suspensory ligament maintains the clitoris in a "bent" position with the glans and distal elements oriented inferiorly. The principal blood supply to the glans clitoris is via the dorsal clitoral arteries, a branch of the pudendal artery. Additional blood supply to the erectile bodies of the clitoris is derived from perineal arteries (bulbar and urethral branches) and the deep arteries of the clitoral bodies (O'Connell et al, 2008). The deep dorsal vein drains the erectile tissues of the clitoris. The clitoral prepuce derives its blood supply from the external pudendal arteries (O'Connell et al, 2008).

The dorsal clitoral nerves are derived from the pudendal nerve and originate near the pelvic sidewall (O'Connell et al, 2005) lateral to the rectum where they branch off from the pudendal neurovascular bundles (Yucel and Baskin, 2004). The paired clitoral nerves travel along the ischium and coalesce superior to the glans clitoris (O'Connell et al, 2005). These nerves extend along the surface of the clitoral tunica but most terminate in the glans clitoris (O'Connell et al, 2005). There is some redundancy of innervations for the glans clitoris via the cavernous nerves (Yucel and Baskin, 2004; Martin-Alguacil et al, 2008). Sympathetic fibers to the clitoris are derived from the hypogastric nerve, which is in turn derived from the paravertebral sympathetic chain ganglia (Giuliano et al, 2002).

The dorsal nerve of the clitoris is the principal somatic sensory innervation of the clitoris and surrounding tissues. The distal clitoral nerves stain positive for cholinergic, nitrergic fibers as well as substance P and calcitonin gene-related peptide (CGRP). Cavernous nerves (containing S2 to S4 parasympathetic fibers from the pelvic ganglia) provide innervations to the erectile bodies of the clitoris (O'Connell et al, 2008). These fibers are positive for cholinergic and nitrergic neurons (Yucel and Baskin, 2004).

Interestingly, in the glans clitoris itself the fibers stain positive only for the sensory neuropeptides substance P and CGRP (Yucel and Baskin, 2004). It is implied that the vasoactive neuronal innervations from cholinergic and nitrergic fibers are relevant primarily to the erectile portions of the clitoris, whereas sensory neurons are of primary importance in the clitoral glans. Nerve endings in the glans clitoris consist of free nerve endings (sensitive to temperature and light touch) and Pacini corpuscles (sensitive to vibration and pressure) in addition to a number of nerve endings (O'Connell et al, 2005; Martin-Alguacil et al, 2006, 2008).

Clitoral stimulation is typically pleasurable for women and may lead to orgasm; the nature of desirable stimulation however varies from woman to woman and may vary for a woman in different circumstances (Leff and Israel, 1983). Because the clitoris is densely innervated, direct contact may sometimes be uncomfortable for some women (O'Connell et al, 2008).

Internal Genitalia

Like the labia minora, the *vulvar vestibule* is derived from embryonic endoderm (Woodruff and Friedrich, 1985). The vulvar vestibule consists of mucosal tissue that surrounds the vaginal orifice circumferentially from the hymenal ring to the paired labia minora (O'Connell et al, 2008).

The hymen is a circumferential skin structure located immediately proximal to the vaginal introitus. There is variability in hymen appearance but in most cases it has fenestrations to permit passage of menstrual blood. The hymen may rupture with bleeding during vigorous physical activity or with vaginal penetration (O'Connell et al, 2008).

The urethra, although not technically a sexual organ, is in close approximation to the vagina and clitoris, and periurethral tissue may engorge during sexual arousal. The distal urethra also contains glandular elements known as Skene glands, which may produce some fluid during sexual arousal (Goldberg et al, 1983). The content of this fluid has been shown to include prostate-specific

Figure 32-3. A and B, Vulvoscopy photos from two women, ages 27 years and 35 years, who presented with clitoral pain. Both were found to have moderate clitoral phimosis with an inability to visualize the remaining portion of the glans and especially the corona of the glans. Both were diagnosed with glans balanitis secondary to phimosis of the prepuce. Conservative strategies failed to resolve the clitoral pain; both women underwent a dorsal slit procedure that resolved the glans balanitis. C, A 24-year-old woman with no vulvar pathology.

antigen (PSA) (Tepper et al, 1984; Ziviatic and Ablin, 2000) and serum levels of creatinine (Wimpissinger et al, 2007). Some reports have suggested that these glands may be the source for female ejaculate (Goldberg et al, 1983; O'Connell et al, 2008).

Vagina

The vagina is a tubular structure with a mucosal surface that connects to the endodermal tissue of the vulvar vestibule. The vagina extends from the vestibule to the cervix.

The vaginal introitus is the opening from the exterior into the vaginal canal. The vaginal introitus is highly elastic and has a tremendous capacity to stretch during sexual activity and childbirth (O'Connell et al, 2008). The distal one third of the vagina is derived from the urogenital sinus (O'Connell et al, 2008). The proximal two thirds of the vagina is a mesodermal derivative of the müllerian duct (O'Connell et al, 2008).

There are four layers to the vagina; from superficial to deep, these include the mucosa, lamina propria, muscularis, and areolar connective tissue rich in collagen and elastin. There is a rich network of vascular tissue in the lamina propria, which permits engorgement of the vagina with blood during sexual arousal (Musicki et al, 2009). The muscularis layer is composed of outer longitudinal fibers and inner circular fibers (Munarriz et al, 2002a). In premenopausal women, the vagina has a baseline level

of moisture that may allow for sexual intercourse even without additional production of vaginal transudate fluid (van Lunsen and Laan, 2004).

The vagina is acidic at baseline with a pH between 4 and 5 and is colonized with a variety of micro-organisms, predominately *Lactobacillus* and/or other lactic acid-producing species (Eschenbach et al, 2000; Zhou et al, 2004). The acidity of the vagina is maintained in part by the metabolism of glycogen from the vaginal mucosa into lactic acid (Goldstein and Alexander, 2005). More recent evidence has suggested that vaginal epithelial cells may also contribute to vaginal acidity by direct secretion of hydrogen ions by an estrogen sensitive mechanism (Gorodeski, 2005). Perturbations of vaginal pH may be cause or effect of bacterial overgrowth, infection, and vaginal discomfort (Bachmann et al, 1999). Changes in pH and the absence of *Lactobacilli* have been associated with a loss of estradiol (E) effect after menopause; this may predispose women to bladder or vaginal infection with enteric organisms (Bachmann, 1995). Estrogen replacement may reduce these effects (Henriksson et al, 1994).

There appears to be ethnic variability between women with respect to vaginal microbiome (Zhou et al, 2004). These variations are not necessarily pathologic and there may be a cultural/dietary component to some of the variability (Ravel et al, 2011). These differences may also explain (or be explained by) ethnic variations in vaginal pH that have been reported (Ravel et al, 2011).

The vagina is innervated by the pelvic nerves (Schober and Pfaff, 2007), parasympathetic fibers derived from S2 to S4 (Giuliano et al, 2002), and also by the vagus nerve. The vagus is purported to serve as a “bypass mechanism,” by which women who have had spinal cord injury may still experience vaginal and cervical sensation (Komisaruk et al, 2004). Sympathetic fibers to the vagina are derived from the hypogastric nerve, which is in turn derived from the paravertebral sympathetic chain ganglia (Giuliano et al, 2002). In rodent studies the sympathetic fibers to the vagina are localized to the lower thoracic and upper lumbar spinal roots (Nadelhaft and Booth, 1984). The density of nerve receptors is greatest in the distal portion of the vagina (Pauls and Berman, 2002) and on the anterior vaginal wall (Hilliges et al, 1995).

Vaginal blood supply is derived from the vaginal branches of the uterine and hypogastric arteries proximally and from the middle hemorrhoidal and clitoral arteries distally (Salonia et al, 2010).

Cervix and Uterus

The cervix is located at the proximal portion of the vagina and is the inferior-most portion of the uterus. The cervix contains small glands that contribute to vaginal lubrication with arousal. In coital intercourse with intravaginal ejaculation, spermatozoa are transported through the cervical os, which also dilates at parturition to permit passage of the fetus.

The role of the cervix in sexual response is unclear and controversial (Grimes, 1999); some women may enjoy contact with the cervix during sex but many find it uncomfortable. Studies of women after total versus subtotal (i.e., cervix-sparing) hysterectomy are subject to multiple confounders and have not uniformly shown convincing results that support or refute a role for the cervix in sexual function (Grimes, 1999).

The uterus is a muscular pelvic organ that carries the fetus during pregnancy. Uterine contractions occur during orgasm. The hypogastric nerves innervate the uterus and cervix (Berkley et al, 1990; Schober and Pfaff, 2007); there are also fibers of the vagus nerve that appear to innervate the cervix (Komisaruk et al, 2004, 2011).

The uterus is attached to the bilateral fallopian tubes, which terminate in the vicinity of the ovaries. Although not immediately germane to sexual response, the ovaries are obviously essential in reproduction and may lead to sexual problems in disease states (e.g., polycystic ovarian syndrome, etc.) (Goldstein and Burrows, 2008).

Clitoral Bulbs

The clitoral (also known as vestibular) bulbs are bilateral organs located caudad to the clitoris and on either side of the vagina (O’Connell et al, 2005). The clitoral bulbs are confluent in the vicinity of the urethral meatus and track posteriorly along the crura of the clitoris superficial to the pelvic diaphragm and medial to the bulbocavernosus muscles. It does not appear that these structures merge with the glans clitoris (Yang et al, 2006). The clitoral bulbs are erectile tissue but lack a dense tunica albuginea; hence, they may expand a great deal during sexual arousal but do not become rigid because of the lack of an ability to coapt and trap blood.

“G Spot”

In 1950 Dr. Ernst Grafenberg reported the existence of an area on the anterior vaginal wall that was associated with intense sexual pleasure when stimulated (Grafenberg, 1950). This area was subsequently named the “G spot” in his honor and has been the subject of intense societal interest since that time (Goldberg et al, 1983).

For many years the existence of the G spot as a distinct anatomic region has been controversial; anatomic and imaging studies have generally not demonstrated a discrete anatomic region corresponding to a specific gland or organ (O’Connell et al, 2005). However, there is evidence to suggest that the anterior vaginal wall does have a greater density of sensory neurons than the

posterior wall, providing some credence to the idea that this area is erotically sensitive (Hilliges et al, 1995).

More recently, some authors have reported the presence of distinct periurethral tissues that are more developed in women who report pleasure from G-spot stimulation and/or female ejaculation (Wimpissinger et al, 2007). Female ejaculation is itself a controversial topic in that glandular elements capable of producing significant volumes of fluid are difficult to locate radiographically or anatomically in women. Despite this ambiguity, many authors have documented female ejaculation and reported enrichment of PSA (Zavaiacic and Ablin, 2000) and serum levels of creatinine in “female ejaculate” (Wimpissinger et al, 2007). This suggests a glandular source potentially analogous to the male prostate and argues against female ejaculate as urine (Goldberg et al, 1983; Davidson et al, 1989).

The derivation and even the existence of the G spot and female ejaculation are likely to remain controversial. Regardless, some women find direct stimulation of this area pleasurable and others do not. The determination of whether a “G spot” exists is something of an academic question. A woman should be encouraged to determine for herself if stimulation of the anterior vaginal wall (or any other part of her body) is particularly pleasurable.

Pelvic Floor Musculature

The pelvic floor musculature plays a critical role in sexual arousal and response. The pubococcygeus and iliococcygeus muscles are collectively known as the levator ani (LA). The iliococcygeus attaches to the coccyx posteriorly and to the pubic bone anteriorly. The pubococcygeus is anterior to the iliococcygeus and inserts bilaterally at the pubic ramus and forms a muscular sling around the bladder, urethra, vagina, and rectum (Strohbehn, 1998). Some authors divide the pubococcygeus into segments based on visceral attachment; these subdivisions are known as the pubovaginalis, pubourethralis, puboanalis, and puborectalis for the portions attached to the vagina, urethra, anus, and rectum, respectively (Lawson, 1974). The pubococcygeus may also be divided into a transverse portion called the levator plate and a vertical portion called the suspensory sling (Shafik, 2000). The semantic variations in published reports on female pelvic muscle anatomy can complicate interpretation of published research.

The general action of the LA is to draw the urogenital structures of the female pelvis ventrally toward the pubic bone. The LA plays an important role in fixing urogenital organs to the pelvic sidewall. The LA is composed primarily of slow twitch fibers that serve to fix pelvic viscera and to prevent prolapse with exertion. Fast twitch fibers are also present and may serve a role in reacting to sudden increases in intra-abdominal pressure with the Valsalva maneuver (Critchley et al, 1980; Gilpin et al, 1989). Innervation of the LA is primarily derived from the pudendal nerve and S2 to S4 nerve roots (Lawson, 1974).

Genital Anatomy and Self-Image

Any discussion of genital anatomy in women must include an acknowledgment that there is a tremendous diversity of normal vulvar/labial appearance (Lloyd et al, 2005). Many women are unfamiliar with their own genital anatomy and/or have concerns about the “normalcy” of their external genitalia; these concerns may be exacerbated by exposure to “idealized” female genitalia in explicit media and/or by partner criticisms (Boynton, 1999; Herbenick et al, 2011b).

Education and reassurance are often of great benefit when discussing with women the normal variations in genital anatomy. In most cases of distress associated with genital appearance, reassurance is all that is required. In some rare cases, variations of external genital anatomy may predispose women to particular sexual concerns (e.g., redundant labia being tugged on painfully during intercourse, clitoral phimosis, etc.) and these concerns may be amenable to adaptation in sexual practices. In cases where adaptation fails, surgical intervention may be an option (Goldstein and Burrows, 2007).

Figure 32-4. A, Three images showing vulvoscopy examination of the vaginal mucosa at baseline and following sexual arousal. Multiple beadlike droplets of exudative plasma can be seen on the vaginal mucosa following arousal. B, Multiple layers of the vaginal wall.

The female breasts are often linked to sexual responses; physical changes including nipple erection and increased sensitivity are commonly observed in studies of sexual arousal in women. **Studies indicate that the majority of women enjoy stimulation of the breasts and nipples as part of sexual activity** (Levin and Meston, 2006). The nature of breast stimulation that is pleasurable varies greatly from woman to woman and may change for a given woman dependent on context. Breast stimulation may be uncomfortable for some women, particularly during pregnancy or lactation (Leeman and Rogers, 2012).

Stimulation of the anus is pleasurable for some women, and slightly more than one third of women in studies report a history of anal sex (Chandra et al, 2011; Mercer et al, 2013). This

stimulation may take the form of external stimulation of the anus or anal penetration with a penis, finger, or other object. As the anal sphincter is normally tightly coapted and the anus does not produce lubrication, application of some form of lubricant and gentle, slow stimulation is advisable during sexual activity involving the anus (Herbenick et al, 2011a). Caution should also be exercised to avoid transfer of coliform bacteria from the rectum to the vagina, as this may increase the risk of urinary tract or vaginal infection.

Individual women may have intense arousal response to stimulation of parts of their body that are not generally deemed erogenous. Self-exploration can be a powerful means of discovering ways to intensify sexual pleasure and is recommended for sexual problems by the majority of sex therapists (Basson et al, 2010b).

The nitric oxide (NO)/cyclic guanosine monophosphate (cGMP) pathway contributes to clitoral erection and vaginal vasodilation with sexual arousal (Burnett et al, 1997; Kim et al, 2003). The cavernous nerves to the clitoris and the vaginal tissues stain positive for neuronal nitric oxide synthase (nNOS) (Burnett et al, 1997; Yucel and Baskin, 2004). NO activates guanylate cyclase, which produces cGMP. cGMP activates numerous downstream effectors, the net effect of which is to sequester calcium and to reduce contraction of smooth muscle in the clitoral and vaginal circulation and within the vaginal wall. The production of NO in genital tissues may also be mediated by the activity of endothelial nitric oxide synthase (eNOS). The expression of eNOS in genital tissues is under the regulation of E (Musicki et al, 2009).

Nitric oxide synthase (NOS) uses the amino acid arginine as a substrate; the enzyme arginase breaks arginine into ornithine and thus reduces the available pool of substrate for NOS. Based on this, it has been hypothesized that arginase may oppose vascular engorgement in the female genital response but the precise mechanisms of this are unclear (Kim et al, 2004). Preliminary data have suggested that arginase inhibitors may enhance genital responses in vitro but in vivo studies are scant (Cama et al, 2003).

Vasoactive intestinal polypeptide (VIP) is also involved in genital vasodilation (Blank et al, 1986). VIP has also been detected in the clitoris and plays a role in clitoral erection (Martin-Alguacil et al, 2006).

Prostaglandins and other local tissue effectors (histamine, tachykinins, etc.) play a role in female genital response, particularly with respect to sensation (Martin-Alguacil et al, 2006). This modulation of sensation may account for changes in the nature of genital stimulation desirable to a given woman during sexual response.

Phosphodiesterase type 5 (PDE5) is present in human female genital tissue and is responsible for the breakdown of cGMP. Inhibitors of PDE5 (PDE5I) promote vasoconstriction and decreased vaginal blood flow. PDE5I are active in human female genital tissue and promote vascular engorgement. Side effects of PDE5I include flushing, congestion, headache, and visual changes (Park et al, 1998).

Although PDE5I will reliably exert genital effects in women (Laan et al, 2002; Basson and Brotto, 2003), published literature supporting the clinical use of PDE5I for the management of sexual arousal problems in women is not robust (Chivers and Rosen, 2010). Lack of predictable concordance between genital and subjective measures of female sexual response may partially explain this observation (Laan et al, 1995; Chivers et al, 2004, 2007, 2010). Ambiguity regarding the appropriate classification of female sexual dysfunction (FSD) has also plagued clinical trials of PDE5I in women with sexual concerns (Chivers and Rosen, 2010). Finally, the marked placebo response noted in most trials of medications for sexual function also contributes to a difficulty in demonstrating the superiority of PDE5I to placebo in controlled trials (Rosen et al, 2007; Bradford and Meston, 2009, 2011; Bradford, 2013).

Additional molecules relevant to sexual response in the female genitalia include neuropeptide Y, galanin, calcitonin gene-related peptide, substance P, peptide histidine methionine, and histidine valine (Jorgensen et al, 1989). The role of these various cellular messengers has not been clearly elucidated (Giuliano et al, 2002; Traish et al, 2010).

Neuroanatomy

Current understanding of the neurophysiology of female sexual response is somewhat limited. Extrapolation to women of neurobiologic findings in men is scientifically unsound (Giuliano et al, 2002; Schober and Pfaff, 2007). Any parallels between female and

male sexual response should be treated as hypothetical until they have been investigated.

Central Nervous System

Processing of erotic stimuli and regulation of sexual response occurs in the central nervous system (CNS). Psychogenic arousal is typically derived from visual, aural, and/or olfactory stimuli that are interpreted as arousing (Schober and Pfaff, 2007); this may include the presence of an attractive partner, exposure to erotic visual or auditory materials, erotic thoughts or memories, or scents that are linked to arousal or sexual response (Schober and Pfaff, 2007).

Brain centers deemed particularly important to the integration of sexual desire and arousal responses for women include the medial amygdala, the stria terminalis, the ventromedial nucleus of the hypothalamus, and the paraventricular nucleus (PVN) (Veening and Coolen, 1998; Schober and Pfaff, 2007). A connection has been demonstrated between the clitoris and the PVN in female rats (Marson, 1995) and activation of this brain region has been demonstrated during copulation studies (Flanagan-Cato and McEwen, 1995). Visual sexual stimuli appear to be processed by relays from the vision centers to the lateral geniculate nucleus (Schober and Pfaff, 2007).

It is postulated that some brain regions important in male sexual response (e.g., the medial preoptic area [MPOA]) are less important in female sexual response (Schober and Pfaff, 2007). However, it has been demonstrated that the MPOA is important in mate selection by female rats (Whitney, 1986), and a study reported that stimulation of the MPOA in female rats leads to an excitatory genital response (Giuliano et al, 2001).

Brain centers activated in orgasm include the medial amygdala, the anterior cingulate, the frontal, parietal, and insular cortices, and the cerebellum (Komisaruk et al, 2004). The left anterior insula has been linked to sensations and intensity of orgasm; it is thought that this region is linked to feelings of closeness and attachment to the partner (Ortigue et al, 2007). It has been hypothesized that reduction in CNS activity in brain regions is associated with embarrassment or suppression of sexual response (e.g., the superior and middle temporal gyri) (Maravilla and Yang, 2008). Decreased activity in these regions may facilitate sexual response by removing CNS inhibition (Salonia et al, 2010).

The spinal cord receives sensory afferent information from the pelvic, hypogastric, and pudendal nerves (Martin-Alguacil et al, 2006). Information is transmitted via interneurons within the spinal cord gray matter and to the thalamus and brain stem via ascending spinothalamic and spinoreticular columns (Lee and Erskine, 1996; Marson and Foley, 2004). Integration of these ascending pathways occurs in the medullary reticular formation and the lateral vestibular nucleus; from these centers, signals are relayed to the ventromedial hypothalamus and other brain areas (Schober and Pfaff, 2007). Brain centers including the nucleus paragigantocellularis and the locus caeruleus are projected to the lumbar spinal cord and they modulate spinal cord responses (Martin-Alguacil et al, 2006). The lumbosacral spinal cord is an important center for integrating and coordinating central and peripheral nervous system responses into a coordinated sexual response (Schober and Pfaff, 2007).

A variety of molecular messengers, likely relevant to genital and sexual function, have also been localized to the lumbar spine. Interestingly, expression of these molecular messengers appears to vary between men and women (Martin-Alguacil et al, 2006). It should not be assumed that the regulation of female sexual response is of necessity entirely similar to male sexual response. Further research is needed (Giuliano et al, 2002).

In animal models, stimulation of the serotonergic 5-HT_{1A} receptors in the MPOA and/or midbrain tends to inhibit lordosis behavior, suggesting a suppressive effect on sexual activity (Uphouse et al, 1992). Interestingly, activation of other peripheral serotonin receptors (5-HT₁ and 5-HT₃) may induce vasodilation (Cappelli-Bigazzi et al, 1991; Skop and Brown, 1996). The serotonin-mediated control of vasculature tone is complex and incompletely understood, particularly as it pertains to female sexual function (Frohlich and Meston, 2000).

Serotonin also plays a role in peripheral neurotransmission involving the genital organs (Berkley et al, 1993), reflex contraction of uterine smooth muscle (Maigaard et al, 1986; Frohlich and Meston, 2000), and serotonin levels have been shown to fluctuate throughout the menstrual cycle (Schreiner-Engel et al, 1981; Rapkin et al, 1987).

contraction of genital vasculature and suppression of arousal response are mediated by norepinephrine (Giuliano et al, 2002).

The administration of the adrenergic antagonist phentolamine has been shown to increase objective parameters of female sexual response (Rosen et al, 1999b); adrenergic agents have also been shown to reduce clitoral engorgement (Pescatori et al, 1993). Hence, there is indirect evidence of a role for the adrenergic neurotransmitter norepinephrine in opposing genital vasodilatory responses in humans as well. This effect is parsimonious with the known effects of adrenergic neurotransmitters in other vascular tissues, and this suggests that basal sympathetic tone to the female genital organs is mediated in large part by norepinephrine (Giuliano et al, 2002).

Other Neurotransmitters Relevant to Sexual Response

VIP plays a role in the CNS with respect to pair bonding during noncoital sexual intimacy (Eriksson and Uvnas-Moberg, 1990). This relationship is in addition to the important peripheral effects of VIP in the female genitalia. γ -Aminobutyric acid (GABA) and glutamate are neurotransmitters (inhibitory and excitatory, respectively) (Giuliano et al, 2002) that play a role in regulating interneuronal fibers at the level of the lumbar spinal cord. These interneurons integrate sexual stimuli (Schober and Pfaff, 2007). Acetylcholine plays a relatively minor excitatory role in female genital response. Anticholinergics have little effect on vaginal blood flow in humans (Wagner and Levin, 1980) and animals (Giuliano et al, 2001).

Hormonal Aspects of Sexual Response

Estrogens

Estrogens are the primary “female” sex steroids and estradiol (E) is the most significant of these. Estrogens act by binding to estrogen receptors (ERs). The alpha subtype (ER- α) is the most common isoform in the genitalia, although the beta subtype (ER- β) has also been detected (Hodgins et al, 1998; Saunders et al, 2000).

Estrogens have CNS effects relevant to sexual response (Rachman et al, 1998). Estrogens maintain female genital tissue integrity and thickness (Martin-Alguacil et al, 2006). Peak E levels occur at the midpoint of the menstrual cycle and are associated with maximal vaginal mucosal thickness and glycogen content; it is parsimonious to hypothesize that this is an evolutionary adaptation to facilitate sexual activity during the fertile window (Farage and Maibach, 2006). With menopause there is a marked decline in genital sensitivity, vaginal thickness, collagen content, baseline moisture, and acidity (Fig. 32-5 on the Expert Consult website). This may occur because of downregulation of VIP activity in the hypoestrogenic environment (Farage and Maibach, 2006; Martin-Alguacil et al, 2006).

Women with serum E levels less than 50 pg/mL have a markedly increased risk of vaginal dryness and pain during sexual activity (Sarrel, 2000). Menopausal women who start E hormone replacement (vaginal or systemic) typically report increased sexual interest and enjoyment, less sexual pain, and greater orgasmic potential (Nathorst-Boos et al, 1993; Dennerstein et al, 2005). Similar findings have been reported in women using selective estrogen receptor modulators (SERMs) and the novel synthetic hormone tibolone (Laan et al, 2001). The benefit of estrogenic therapies in nonselected menopausal women is less clear (Nastri et al, 2013). E replacement has been associated with increased risk of venous thromboembolism; some reports have also suggested that E replacement may predispose women to carcinogenesis (breast or endometrial) and cardiac disease. The issue of E replacement remains controversial (Utian et al, 2008).

E has been shown to enhance sensory fields, nerve density, and tissue mechanical properties that drive sensitivity in the genital tissues of experimental animals (Komisaruk et al, 1972; Kow and Pfaff, 1973; Pfaff et al, 1977). This effect may be mediated by E modulation of local sensory mediators important in genital sensation (Martin-Alguacil et al, 2006). E has also been shown to effect

recovery of pudendal nerves after trauma in animal models (Kane et al, 2004).

Although hypoestrogenism is associated with changes in sexual function and activity, many women with low serum estrogen report sexual interest and sexual activity that is satisfying (Cawood and Bancroft, 1996; Avis et al, 2009). Furthermore, postmenopausal women often maintain the capacity for vaginal lubrication; change in vaginal blood flow with sexual arousal is similar in healthy pre- and postmenopausal women (Laan and van Lunsen, 1997). With adequate sexual stimulation, vaginal lubrication may compensate for decreased baseline vaginal moisture (Berman et al, 1999). Postmenopausal sexual satisfaction is most strongly predicted by satisfactory sexual activity before menopause (Bachmann and Leiblum, 1991). Ergo, estrogen status is important but not entirely predictive of sexual satisfaction in women (van Lunsen and Laan, 2004). Sexual distress in older women may also be lower in some cases because of declines in sexual interest, which reduces the psychoemotional toll of declines in sexual functionality common in aging (Hayes and Dennerstein, 2005).

Testosterone

Testosterone (T) is the “male” sex hormone, but it is present in small quantities in women. Approximately 50% of circulating T in premenopausal women is produced by the adrenal glands with the remaining 50% produced by the ovaries (Judd et al, 1974). Activity of T is influenced by binding to sex hormone-binding globulin (SHBG) and weak binding to albumin. T bound to SHBG tends not to exert biologic effects (Bachmann and Oza, 2006).

Androgen receptors (ARs) are present in female genital tissues (Hodgins et al, 1998). The activity of the AR is of critical import in determining androgenic response to circulating T. Variations in AR activity result from a variety of factors; there has been intense interest on the trinucleotide (CAG) repeats on the AR primer (Chamberlain et al, 1994). Longer CAG repeats tend to reduce activity of the enzyme; this may influence the efficacy of serum T in producing clinically meaningful effects, although evidence to support this hypothesis in women is currently scant (Davison and Davis, 2011).

There is evidence that T plays a role in sexual appetitive behavior, maintenance of genital tissue integrity, and sexual arousal responses in women (Van Goozen et al, 1997; Riley and Riley, 2000; Traish et al, 2010). Low androgen levels are associated with a decline in sexual activity and desire (Bachmann and Leiblum, 1991). However, the relationship between T and sexuality in women is inconsistent (Davis et al, 2005; Brotto et al, 2010).

T levels decline with age in women although the rate of decrease slows after age 35. Because a substantial proportion of women's androgens are derived from adrenal sources, the decline in T production with menopause is gradual. The postmenopausal ovary produces T; women who are surgically menopausal after oophorectomy experience a more marked decline in T compared to women who are naturally menopausal (Davison et al, 2005). As SHBG levels rise with age, many postmenopausal women will experience a decline in bioavailable T, particularly if they use supplemental estrogen (another common cause of rising SHBG) (Bachmann and Oza, 2006).

Exogenous androgen increases sexual desire, arousal, and orgasmic response in women with low baseline serum androgen levels (Braunstein et al, 2005; Somboonporn et al, 2005; Shifren et al, 2006; Blumel et al, 2008; Davis et al, 2008b). A role for exogenous T in management of vulvovaginal atrophy has been demonstrated in some small studies (Witherby et al, 2011). Potential adverse effects of T treatment include application site reactions, hirsutism, acne, vaginal bleeding, and dyslipidemia (Braunstein et al, 2005; Braunstein, 2007). There have also been substantial concerns about the risk of increased incidence of carcinogenesis, particularly hormone-sensitive tumors such as breast and endometrial (Braunstein, 2007). The majority of long-term observation studies have not suggested a significant increase in cancer risk for women taking exogenous T for as long as 2 years (Braunstein, 2007; Davis et al, 2009; Jick et al, 2009).

Figure 32-5. A, Vulvoscopy photo of a 59-year-old woman in menopause for 8 years without hormone replacement. She presented with dyspareunia, burning, itching, and dryness of the vulva consistent with vulvovaginal atrophy. In vulvovaginal atrophy, there is genitourinary atrophy with vaginal pH greater than 5.0, blanching of the vaginal mucosa, diminished introital elasticity, telescoped and patulous urethral meatus, as well as urethral glans tissue, concavity, and involution of the vestibule and increased erythema of the posterior fourchette. B, For comparison, a normal vulvoscopy photo of a 38-year-old woman with a healthy reproductive cycle who presented for discussion of contraceptive options.

An association has been reported between high serum androgen level and cardiovascular disease in women (Janssen et al, 2008). However, a 19-year longitudinal study in postmenopausal women did not detect any link between sex hormone levels and cardiovascular mortality (Barrett-Connor and Goodman-Gruen, 1995). Additionally, a long-term study in 365 female-to-male (FtM) transgender persons receiving supplemental androgen did not detect an increase in risk of cardiovascular disease (Asscheman et al, 2011). Additional data on long-term safety are needed (White et al, 2012).

T for women is off-label use in the United States. Careful discussion and documentation between patient and provider are essential if T supplementation is considered in women (Shifren et al, 2006; Wierman et al, 2010).

Dehydroepiandrosterone

Dehydroepiandrosterone (DHEA) is a weak androgen produced by the adrenal cortex. DHEA may be converted into androstenedione, a precursor to both T and E. Like T, DHEA levels tend to decline with increasing age (Davison et al, 2005).

In a study of more than 1000 Australian women, those with sulfated DHEA levels in the bottom 10th percentile experienced an increased risk for lower sexual desire, arousal, and responsiveness (Davis et al, 2005). However, the role of supplemental DHEA in female sexual function is not established (Arlt, 2004; Davis et al, 2011).

The Menstrual Cycle and Sexuality

Menstruation is under the regulation of several hormones, principally E (Bancroft and Graham, 2011). E gradually increases during the follicular phase and causes endometrial proliferation. Stability of the endometrium is maintained by the action of progesterone (P). E leads to a surge in LH production from the pituitary, triggering ovulation and initiating the luteal phase. T levels rise during the follicular phase to a peak around the time of ovulation (Roney and Simmons, 2013). In many women sexual desire peaks during the ovulatory phase (Burlinson et al, 2002); these data are subject to several limitations (Brown et al, 2011) and there is substantial variability among women (Burlinson et al, 2002; Sheldon et al, 2006; Wallen and Lloyd, 2011). After ovulation, E, P, and T gradually decline, leading to sloughing of the endometrium and the beginning of the menstrual phase (Wallach, 1970).

Hormonal contraceptives (oral, subcutaneous, injectable) modulate E to prevent ovulation. Hormonal contraceptives tend to reduce serum T (Coenen et al, 1996; Kovalevsky et al, 2010; Battaglia et al, 2012) and raise serum SHBG (Warnock et al, 2006). This synergistically lowers bioavailable T and may contribute to sexual side effects (Coenen et al, 1996). **Specific changes reported in some women using hormonal contraception include decreased sexual desire, atrophy and pain in the labia and genital tissues, decreased intercourse frequency, and decreased orgasmic function** (Fig. 32-6 on the Expert Consult website) (Battaglia et al, 2012). Some women tolerate hormonal contraception without discernible perturbation of their sexual life; several studies have reported no objective or subjective changes in sexual function in women using hormonal contraceptives (Shirtcliff et al, 2002; Greco et al, 2007; Flyckt et al, 2009; Kovalevsky et al, 2010; Lee et al, 2011). However, some women may be particularly sensitive to the androgen-lowering effects of hormonal contraception (Bancroft and Graham, 2011). The benefits of hormonal contraceptives for birth control and other concerns (e.g., dysmenorrhea, acne, etc.) should be balanced against these potential risks. Use of an agent with androgenic effects may be of benefit in women with sexual issues related to hormonal contraception (Davis et al, 2013).

Pelvic Floor Musculature

Contraction of the LA produces straightening and dilation of the vagina and elevation of the cervix (Shafik, 2000). The bulbospongiosus and ischiocavernosus muscles, located superficially and

circumferential to the distal vagina, contract to increase distal vaginal tone and pressure during sexual arousal and orgasm (Shafik, 1993).

Kegel and Graber reported that the strength of the LA is directly related to sexual pleasure and orgasmic response in women (Kegel, 1952; Graber and Kline-Graber, 1979). Hypotonicity of these muscles may impair sexual response (Graziottin, 2005) and contribute to sexual problems resulting from pelvic organ prolapse and incontinence (Strohbehn, 1998). Hypertonicity of the LA may predispose women to pain with vaginal penetration (Rosenbaum and Owens, 2008).

MENTAL ASPECTS OF SEXUAL RESPONSE IN WOMEN

Mental and physical arousal may occur independently of one another in women. Women exposed to erotic imagery consistent with sexual orientation and preference typically experience subjective arousal and increased vaginal blood flow. Women may also have genital responses to sexual imagery that is mentally unappealing (e.g., images of the nonpreferred gender, images of nonpreferred sexual activities, etc.) despite the absence of subjective arousal (Laan et al, 1995; Chivers et al, 2007).

Additional information on sexual arousal in women is available on the Expert Consult website.

KEY POINTS: FEMALE SEXUAL RESPONSE

- Sexual response in women may be triggered by a number of intrinsic or extrinsic factors.
- NO, VIP, and a variety of other cellular messengers play important roles in female genital arousal responses.
- The CNS integrates erotic stimuli and exerts control of genital responses during arousal.
- E and T play important roles in maintaining genital tissues and modulating sexual response.
- Psychological, emotional, and mental factors play a substantial role in sexual response.

EVALUATION OF SEXUAL WELLNESS IN WOMEN

History

Sexuality and sexual health are sensitive topics and many patients (particularly older women) are hesitant to discuss these topics with their health care providers (Roos et al, 2012). Discomfort may stem from personal embarrassment or shame about sexuality, fear of embarrassing the provider, a sense that nothing can be done, a sense that sexual dysfunction is not a medical problem and/or not a significant problem to be addressed, or a simple lack of time during health care encounters (Nicolosi et al, 2006b). Unfortunately, many providers also have difficulty initiating conversations about sex for reasons similar to those given by patients (Merrill et al, 1990; Tsimtsiou et al, 2006). Many providers also report a lack of training in how to appropriately address sexuality with patients (Parish and Rubio-Aurioles, 2010; Shindel et al, 2010).

Sexual health inquiry can be incorporated into a general urologic clinic visit. Normalizing statements (e.g., "Many patients have questions or concerns about their sexual life") may help the patient to feel at ease discussing sex issues (Sadovsky et al, 2006). A simple, open-ended question (e.g., "What concerns or questions do you have about sexuality?") is recommended as an initial screen (Kingsberg and Althof, 2009). Yes/no questions (e.g., "Are there any problems with your sexual life that you wish to discuss with me?", "Are you satisfied with your sexual life?", "Are you having any bothersome sexual issues?") may be a more expedient and practical means to screen for sexual concerns in some contexts (Roos et al, 2012); if an affirmative response is provided to these

Figure 32-6. Hormonal contraceptive users often show four vulvoscopy findings. Shown are vulvoscopy photographs of a 22-year-old woman on hormonal contraceptive agents. Hormonal contraceptives may cause elevation of sex hormone-binding globulin and a reduction of free testosterone. This may result in glans clitoris atrophy (A), erythema of the minor vestibular glands (B), and limited robust periurethral tissue (D). C, Labial resorption.

A meta-analysis of studies on sexual arousal indicated that there is robust correlation between subjective arousal and penile erection in the male (correlation coefficient = 0.66), whereas the correlation between subjective arousal and genital vasoengorgement (correlation coefficient = 0.26) in women is much less (Chivers et al, 2010). These observations indicate a substantial potential for a disconnect between subjective and objective sexual arousal in women. In a forensic sense, these data may explain why some women experience genital responses such as vaginal lubrication in the context of non-consensual sexual activity (e.g., rape) (Levin and van Berlo, 2004). Various theories have been advanced on how this may be an evolutionary adaption to ensure adequate lubrication (and hence reduced risk of vaginal trauma) even in the context of undesired sexual activity (Chivers and Rosen, 2010).

Despite this biologic observation, interpersonal and psychosocial factors are tremendously important in the sexual response for women. Psychological and emotional responses modulate

how a woman expresses her sexuality and how she responds to sexual initiation from a partner. Women with sexual issues are more likely to have dysfunctional sexual beliefs (e.g., “I’m not turned on” or “sex always hurts”) compared to sexually healthy women (Klaassen and Ter Kuile, 2009; Nobre, 2009). These responses are rooted in psychology but exert physical effects by sympathetic and CNS processes. Interpersonal issues are frequently more important than biologic issues in women’s sexual response (Avis et al, 2000; Dennerstein et al, 2005). Other reports have confirmed the primacy of the marital relationship and general health over menopausal status as predictors of satisfying sexual function (Avis et al, 2000; Dennerstein et al, 2005). Historically these issues have been considered central to sexuality in women and of lesser import in men; one may hypothesize that the dearth of biomedical understanding about female sexuality (and subsequent dearth of nonpsychological treatment options) may play a role in fostering this concept.

screeners, follow-up with open-ended questions will likely produce more nuanced and informative responses (Kingsberg and Althof, 2009).

Allowing the woman to voice any concerns she has about her sexual life and satisfaction is one of the most basic but critical interventions that providers may make on behalf of sexual wellness. **The opportunity to discuss sexuality issues with a professional may substantially decrease sex-related distress (Goldstein and Alexander, 2005).**

Additional advice on taking a sexual history is available in the online supplement.

Surveys

Validated sexuality surveys are simple, unobtrusive, and reliable (Rosen, 2002; Kingsberg and Althof, 2009). In clinical practice, these instruments are useful as means to initiate a conversation about sexual issues (Clegg et al, 2012). **Survey instruments cannot replace a detailed history and physical examination (Kingsberg and Althof, 2009).** A 2010 study indicated that some female partners of men with ED had persistently low survey metric scores despite increases in sexual satisfaction (Conaglen et al, 2010).

Information on survey instruments is available on the Expert Consult website.

Evaluation of the Partner

Sexual distress is linked to incompatibility with the partner (Witting et al, 2008). **Hence involvement of the sexual partner is critical in the management of any sexual health concern.** Education of the partner may be of particular importance given the generally low knowledge of female sexual response in the community (Goldstein and Alexander, 2005).

Additional information on partner evaluation is available in the online supplement.

Physical Examination

A general physical examination including vital signs is required. The patient should be assessed for evidence of endocrinopathy, nerve injury, diabetes, or obesity (Goldstein and Alexander, 2005; Basson et al, 2010b). **Evaluation of the genitals should start with careful inspection of the external genitalia including mons pubis, labia majora, labia minora, clitoris, and vulvar vestibule. This superficial examination may show genital lesions, erythema that may predispose to sexual pain disorders, redundancy of the labia, or atrophy of the external genitalia (Fig. 32-7 on the Expert Consult website) (Goldstein and Alexander, 2005; Basson et al, 2010b).** Vulvar skin conditions are common and can lead to a variety of sexual concerns. Examples include eczema, psoriasis, contact dermatitis, fungal infections, aphthous ulcers, and drug reactions.

Some dermatoses are specific to the vulva and are described on the Expert Consult website.

Testing for genital neuropathy may be accomplished by application of heat/cold stimuli, vibration, and/or application of a toothpick or small pin. A simple assessment for urinary incontinence (cough test, Q-tip test, etc.) is warranted. Urinary symptoms are associated with sexual problems and are within the scope of practice for urologists to manage.

Bimanual examination of the vagina is performed to assess for pelvic organ prolapse and ovarian pathology (Goldstein and Alexander, 2005). Assessment of the LA should be included as part of the bimanual examination (Rosenbaum and Owens, 2008). A speculum examination should be considered.

Assessment of vaginal pH is a simple, inexpensive test. High pH implies E deficiency and/or disruption of the normal vaginal microbiome; this may have relevance to recurrent infection, vulvovaginal atrophy, or other issues and should be performed routinely (Bachmann et al, 1999).

Serum and Other Laboratory Studies in the Evaluation of Sexual Wellness

The role of serum studies in evaluation of female sexual wellness is controversial (Goldstein and Alexander, 2005; Basson et al, 2010b). Serum chemistry, lipids, and glycosylated hemoglobin should be assayed, as these are low-risk tests for common problems potentially relevant to female sexual function. **Assessment of sex steroids, particularly serum E and T, should be considered if there is concern for significant endocrinopathy (Utian et al, 2008; Kingsberg, 2009).**

Serum T testing is controversial because of questions of relevance and precision of results; most widely available assays for T are not precise at the levels typical in women (Stanczyk et al, 2003; Bancroft and Graham, 2011). The timing of assay with respect to menstrual cycle should be clearly defined. T should be assayed in the morning between days 8 and 14 of a 28-day menstrual cycle (Davison and Davis, 2011). Mass spectroscopy is a preferred means for assessing T levels in women but is typically not available outside of research settings (Stanczyk, 2006). Radioimmune assay (RIA) has been shown to possess acceptable precision in quantifying androgen levels in women. The decision to measure serum T should only be made after consultation with the patient about the unknowns and with a clear sense of what will be done with the data if the test result is concerning for androgen insufficiency (Bachmann et al, 2002; Bachmann and Oza, 2006).

In the setting of very low sex steroid levels, prolactin may be assessed. Elevated prolactin is associated with decreased sexual desire and suppression of serum T levels (Atis et al, 2010). Assay of hormones such as DHEA (Munarriz et al, 2002b) and dihydrotestosterone (DHT) may be considered, but the usefulness of these tests is unclear (Davis et al, 2011).

Additional information on physiologic and sensory testing is available on the Expert Consult website.

KEY POINTS: EVALUATION OF SEXUAL WELLNESS IN WOMEN

- A complete history (medical, sexual, partner, etc.) and thorough physical examination (particularly of the genitals) is fundamental to evaluation of sexual wellness in women.
- Many patients are reticent to ask questions about sex; providers should initiate conversations about sexuality.
- Questionnaires and adjunctive testing are of benefit in some cases but do not replace history and physical examination.

SPECIAL POPULATIONS

Pregnancy

Pregnancy has biologic and psychological ramifications for a woman's sexuality (Farage and Maibach, 2006; Pauleta et al, 2010). **Sexual activity is generally safe in pregnancy.** Adaptation to the physical and emotional challenges of gravidity influence a woman's experience of her sexuality. Obstetrical involvement and advice are critical (Millheiser, 2012).

Sexual problems are generally most common in the third trimester (Leite et al, 2009). Women in the later stages of pregnancy may find some sexual positions uncomfortable; these may in some cases be resolved by use of alternative sexual positions or assistive cushions/furniture. Caution should be exercised when considering sexual activity in women with a history of cervical incompetence; repeated trauma to the cervix from vaginal penetration and prostanoids in semen may theoretically contribute to increased risk of preterm labor.

Delivery may be traumatic to the vulva and perineum. Vaginal tears, operative vaginal delivery, and episiotomy may be a source of persistent pain during intercourse with larger tears portending

A thorough history is the cornerstone of evaluation for a woman with sexual concern(s). Sexual, medical, and psychological issues should be assessed; in the situation where the clinician does not have training for in-depth discussion of sexuality, an appropriate referral should be considered (Goldstein and Alexander, 2005; Basson et al, 2010b).

The precise nature of the sexual concern, any associated symptoms, chronology, presumed or defined trigger events, exacerbating or relieving factors, and previously attempted treatments should be elicited (Kingsberg and Althof, 2009; Basson et al, 2010b). It is prudent to avoid assumptions about sexual orientation and/or partner status. Gender-neutral pronouns should be used until the gender of the patient's partner(s) is elucidated. Even in the absence of intent, assumptions about partner gender may make patients uncomfortable and/or fearful to disclose the nature of their sexual lives, particularly if they have a non-normative sexual orientation.

It is desirable to be aware of the patient's perceptions and beliefs on sexuality as this may markedly influence their perception of any sexual issues; women from deeply religious backgrounds are likely to have conservative beliefs on sexuality (Ahrold et al, 2011) and may be more reticent about discussing these issues with a provider. It is always desirable to be sensitive to the patient's sexuality-related beliefs, be they conservative or liberal. Means to improve patient/provider communication about sex is a fertile ground for further research and development but is beyond the scope of this chapter.

An assessment of sexually transmitted infections (STIs) risk behaviors should be included in any sexual wellness consultation (Sadeghi-Nejad et al, 2010). Pre- or perimenopausal women who are involved with a male partner(s) should be asked what (if any) means they are using for contraception.

Female Sexual Function Index

The most widely used and cited research in urologic sexual medicine is the Female Sexual Function Index (FSFI). The FSFI is a 19-item questionnaire that assesses 6 domains of female sexual experience (desire, arousal, lubrication, orgasm, satisfaction, and pain). Each domain is scored on a scale of 0 to 6 points with the exception of the desire domain (scored from 1.2 to 6) and the satisfaction domain (scored from 0.8 to 6). The instrument thus has a range of 2 to 36, with 36 representing a “perfect” score (Rosen et al, 2000). An abbreviated six-item version of the FSFI has been reported (Isidori et al, 2010). The FSFI was validated for use in heterosexual women; versions of the FSFI have been validated for use in lesbian women (Tracy and Junginger, 2007), although these have not been widely used in research (Shindel et al, 2012).

In most studies, a total FSFI score of less than 26.55 has been used as a marker for a higher risk of sexual dysfunction (Wiegel et al, 2005). A specific cutoff for the diagnosis of hypoactive sexual desire disorder (HSDD) using the two-item desire domain of the FSFI was reported; on a scale of 2 to 10, women with a score of 6 or higher on this domain were unlikely to carry the diagnosis (Gerstenberger et al, 2010). Domain-specific cutoff scores for the diagnosis of specific types of sexual “dysfunction” have not been validated for other domains, although various authors have reported arbitrary cutoffs based on speculation.

The FSFI has been shown to be more reliable in predicting treatment success in studies of sexual dysfunction relative to objective measures such as sexual-event logs and vaginal plethysmography (Rellini and Meston, 2006). The FSFI does not specifically assess sexual distress. As sexual distress is an important diagnostic criterion for sexual dysfunction, a sexual dysfunction should not be diagnosed strictly on the numeric criteria of the FSFI. At most, women with low FSFI scores should be considered “at risk” for sexual dysfunction pending complete evaluation.

Profile of Female Sexual Function and Personal Distress Scale

The Profile of Female Sexual Function (PFSF) is a validated, 37-item instrument developed primarily for the assessment of sexual function in postmenopausal women with low sexual desire. It consists of seven domains (sexual desire, arousal, orgasm, sexual pleasure, sexual concerns, sexual responsiveness, and sexual self-image) (Derogatis et al, 2004). The PFSF and a related scale called the personal distress scale (PDS) were combined/adapted into a seven-item brief version (B-PFSF) that also shows good discriminant validity for decreased sexual desire in postmenopausal women (Rust et al, 2007); out of a total possible score of 35, women who score 20 or less on the B-PFSF are at greater risk of low sexual desire.

A follow-up study derived from investigations on T therapy for HSDD indicated that an increase in the sexual desire domain of the PFSF and a 20-point change in the PDS were associated with clinically meaningful changes in HSDD (Derogatis et al, 2009).

Pelvic Organ Prolapse–Urinary Incontinence Sexual Function Questionnaire (PISQ) and PISQ-12

The Pelvic Organ Prolapse–Urinary Incontinence Sexual Function Questionnaire (PISQ) is a validated, 31-item instrument

designed specifically to assess sexual function in women with pelvic organ prolapse and/or urinary incontinence. The PISQ consists of three domains (behavioral emotive, physical, and partner-related) (Rogers et al, 2001). A validated short form of the PISQ (PISQ-12) is more commonly used in clinical research (Rogers et al, 2003).

Female Sexual Distress Scale

The Female Sexual Distress Scale (FSDS) is a 12-item scale that specifically measures sexuality-related distress (Derogatis et al, 2002). This scale differs from some other scales in that it may assess subjective or relationship-based sexual distress in addition to distress related to physical issues in sexual response. A score of greater than 15 is suggestive of significant sexual distress (Meston and Derogatis, 2002). This scale may be of greater use in assessing the subjective components of sexual problems in women but it still cannot be used as a substitute for careful and meticulous history and physical examination.

Arizona Sexual Experience Scale

The Arizona Sexual Experience (ASEX) scale is a validated five-item gender-specific scale that assesses sex drive, arousal, vaginal lubrication, ability to orgasm, and satisfaction from orgasm. Lower scores indicate better levels of sexual function (McGahuey et al, 2000).

Brief Index of Sexual Functioning for Women

The Brief Index of Sexual Functioning for Women (BISF-W) is a 22-item questionnaire that assesses seven domains of female sexual function (sexual thoughts/desires, arousal, frequency of activity, receptivity/initiation, pleasure/orgasm, relationship satisfaction, and sexual problems) (Taylor et al, 1994).

Golombok Rust Inventory of Sexual Satisfaction

The Golombok Rust Inventory of Sexual Satisfaction (GRISS) is a 28-item questionnaire that assesses seven domains of sexual function (avoidance, nonsensuality, infrequency, vaginismus, anorgasmia, noncommunication, and dissatisfaction) (Rust and Golombok, 1986). This scale addresses psychosocial issues primarily and has not been used extensively in biomedical research.

Sexual Function Questionnaire

The Sexual Function Questionnaire (SFQ) is a 31-item questionnaire assessing seven domains of female sexual response (desire, physical arousal, lubrication, enjoyment, orgasm, pain, and partner relationship) (Quirk et al, 2002).

Decreased Sexual Desire Screener

The Decreased Sexual Desire Screener (DSDS) is a brief screening tool designed primarily for use in a clinical setting specifically to assess for symptoms of decreased sexual desire (Clayton et al, 2009). This tool may be of increased use in routine clinical practice related to more comprehensive instruments such as FSFI.

The partner of a woman who has sexual issues is likely to have sexual issues of his/her own (Fisher et al, 2005; Chedraui et al, 2009). There is robust evidence that treatment of erectile dysfunction in the male partner of heterosexual couples leads to positive changes in the female partner's sexual life (Chevret-Measson et al, 2009; Conaglen et al, 2010). Treatment or referral should be considered for a partner with sexual issues. Data on improvement in the sexual lives of same-sex partners are generally lacking but it is logical to hypothesize that similar effects may exist in same-sex relationships.

If there is a significant discrepancy in patient/partner perceptions, or disagreement about the presence of a problem at all, it

may be of value to involve a mental health professional, ideally a qualified sex therapist (Althof, 2010; McCabe et al, 2010). There is a great deal of heterogeneity among self-identified sex therapists so it is beneficial to establish a working relationship with one or more established therapists who have extensive experience and/or training in sexual health issues. A variety of professional organizations certify therapists/counselors for their expertise on matters of sexuality (e.g., the American Association of Sexuality Educators, Counselors and Therapists [AASECT], the Society for Sex Therapists and Researchers [SSTAR], etc.).

Vulvoscopic assessment of two estradiol-dependent organs: (1) labia minora and (2) vaginal epithelium (rugae), and vaginal pH before and after estradiol therapy.

Low Estrogen State

Robust Estrogen State

Labia Minora Normally Meet at Posterior Fourchette

Resorption of Labia Minora

Reduced vaginal rugae. pH >5

Robust vaginal rugae. pH 4

Figure 32-7. Vulvoscopy with photography involves examination of external female genitalia using a binocular vulvoscope/colposcope with magnification and light source. Vulvoscopic photographs show two estradiol-dependent organs in the vestibule before and after estradiol treatment. *Top to bottom*, estradiol-dependent organs including the labia minora and the vagina. In particular, estrogenization of the vagina will show abundant rugae and a pH around 4.0.

Lichen simplex is a condition of skin thickening, erythema, and excoriation that may occur across the labia majora; it is attributable to recurrent pruritus, leading to itching with excoriation and subsequent worsening of the pruritic reaction from recurrent scratching (Salim and Wojnarowska, 2005). Lichen sclerosus is an inflammatory condition thought to include an autoimmune component. The vulvar skin tends to be whitish and atrophy and labial resorption is not uncommon (Fig. 32-8). There is a small but finite risk of malignant transformation in lichen sclerosus (Salim and

Wojnarowska, 2005). Lichen planus (LP) is a condition of violaceous papules and plaques across the genital area. There is an erosive variant of this condition that involves loss of the outer skin layers and development of painful, eroded areas on the labia minora and vulvar vestibule (Fig. 32-9) (Salim and Wojnarowska, 2005). If a lesion is ambiguous or of concern for malignancy, a biopsy should be considered. It is advisable to send a biopsy with a specific diagnostic entity in mind to help guide the dermatopathologist in making an appropriate diagnosis (Salim and Wojnarowska, 2005).

Figure 32-8. A and B, Vulvoscopy photographs from a 43-year-old woman who experienced lichen sclerosus and dyspareunia for more than 15 years.

Figure 32-9. A and B, Vulvoscopy image of a 59-year-old woman with severe dyspareunia and biopsy-proven lichen planus (LP). LP is a disease of the skin caused by inflammation and can affect the vulva and the vagina. Common symptoms include burning, soreness, and itching. LP is also associated with whitish eruption or ulcers in the mouth. LP is thought to be an autoimmune reaction that may have started from an infection or a medication.

Physiologic and/or imaging studies may provide information on sexual response. Whether such testing changes the management of such responses is unclear (Woodard and Diamond, 2009). Sensory testing of the genitals may be accomplished by application of cotton swabs or pins. A biothesiometer (device that applies quantifiable heat and/or vibration) is a more objective means, but the additional information may not change management (Fig. 32-10) (Berman et al, 2001; Woodard and Diamond, 2009).

A 2009 study did suggest that “abnormal” findings were common on genital sensory testing in women with sexual concerns (Helpman et al, 2009). Whether this reliably differentiates women with and without sexual concerns has not been established. Electromyography and biofeedback may be used for assessment of pelvic floor muscles; these technologies are primarily useful in the hands of

specially trained physical therapists (Woodard and Diamond, 2009).

Vaginal plethysmography, Doppler ultrasound, thermography, and angiography have been used to characterize the vascular integrity of the female genitalia (Woodard and Diamond, 2009). Vaginal plethysmography (measurement of vaginal microcirculation) is the most widely used research measure of genital sexual response in women (Geer et al, 1974). Color Doppler ultrasound has been proposed as a means to assess vascular integrity of the clitoris (Lavoisier et al, 1995). Standard parameters for clitoral ultrasound have not been established. Cross-sectional imaging studies such as computed tomography and magnetic resonance imaging may be indicated in certain select cases (e.g., MRI for assessment for urethral diverticulum as a cause for sexual pain) (Suh et al, 2003).

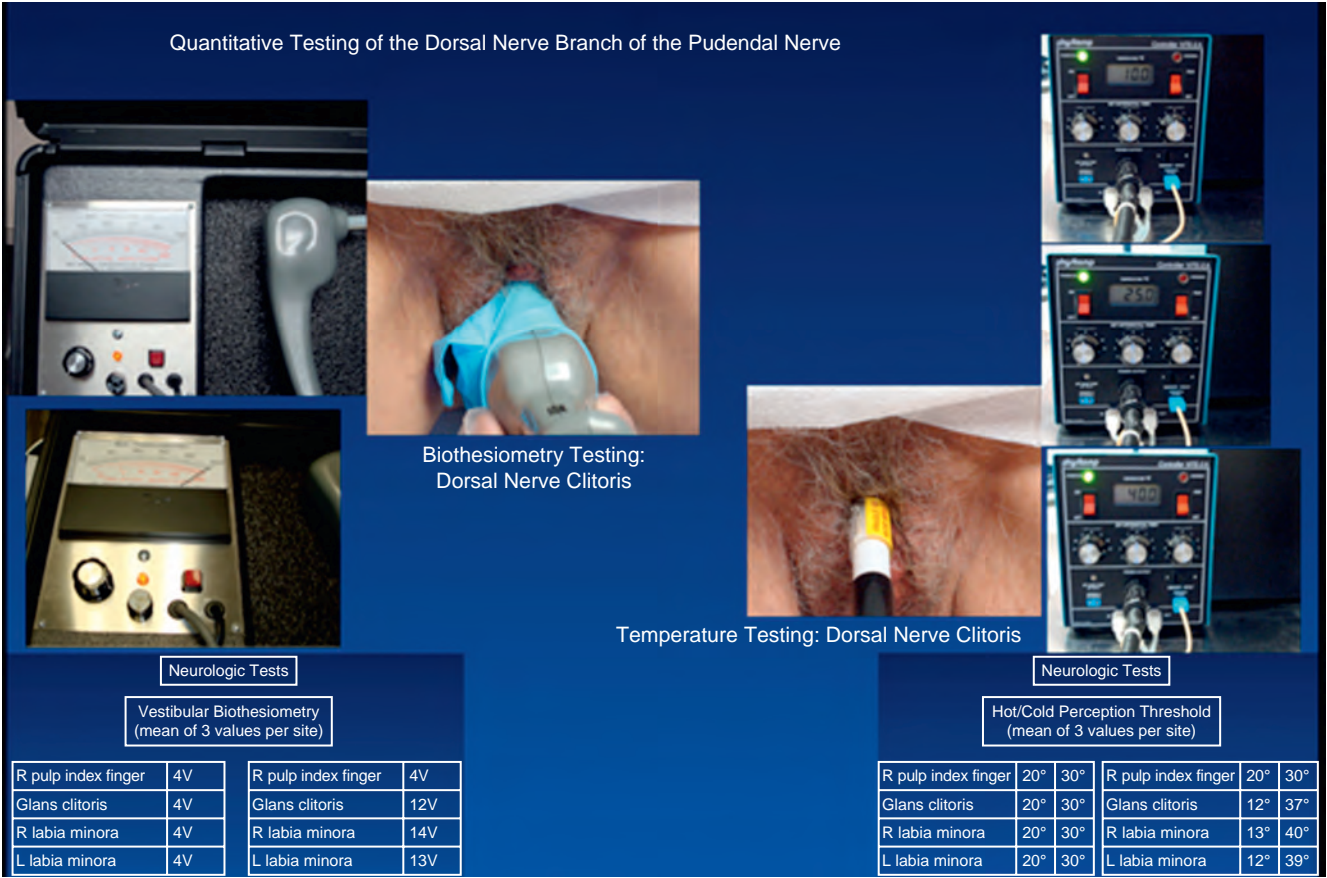

Figure 32-10. Objective sensory nerve testing may be performed using a biothesiometer to determine vibratory perception thresholds (expressed in volts) as displayed (left). Objective sensory nerve testing may be also performed using temperature testing to determine hot and cold perception threshold values (expressed in degrees centigrade) as displayed (right). Quantitative sensory testing measures and values are obtained in a nongenital reference site (pulp index finger) as well as in multiple genital sites such as the glans clitoris (dorsal nerve branches of the pudendal nerve), and the right and left labia minora (the perineal nerve branches of the pudendal nerve)—these latter locations are not shown on the photographs.

greater risk (Signorello et al, 2001; Leeman and Rogers, 2012). There is evidence of pelvic floor denervation and loss of pelvic floor strength in as many as 80% of women giving birth (Allen et al, 1990). It does not appear that there is a significant difference in postpartum sexual function between women who deliver by Caesarean section and those who deliver vaginally (Leeman and Rogers, 2012).

Although about 90% of women have resumed sexual activity by 3 months postpartum (Brubaker et al, 2008), several studies indicate that FSFI scores have not returned to baseline by that time point (Pauls et al, 2008). A major risk factor for this change may be dyspareunia, which has been reported in approximately half of postpartum women at 3 months (Barrett et al, 2000); the prevalence of dyspareunia after 3 months is generally lower (Lal et al, 2011), suggesting a decline in postdelivery dyspareunia with time.

Lactation involves robust production of the hormone prolactin, which tends to suppress estrogens and androgens; this may contribute to declines in sexual desire and dyspareunia from loss of hormone effect on genital tissues (Leeman and Rogers, 2012). The stressors of parenting a newborn and recovery from delivery are short-term barriers to sexual activity, which in some cases may lead to long-term sexuality issues (Pauleta et al, 2010).

Racial/Ethnic Minorities

Some differences in the prevalence of sexual concerns likely stem from cultural factors (Laumann et al, 2005). Perceptions of what is normal will dictate whether a woman believes the sexual issues she is experiencing are problematic (Anderson et al, 2011). Women from conservative or repressive environments tend to report lower levels of sexual satisfaction (Laumann et al, 2006). Awareness of cultural paradigms is useful; however, individual women may not conform to stereotypes of their culture.

A 2005 study reported on differences in sexual concerns of American women of Asian, European, and African ancestry. There was a high prevalence of concerns in women of all racial groups; however, the nature of those specific concerns differed. Compared to white women, African-American women were less likely to express concerns about vaginal lubrication and attractiveness but were more likely to be concerned about sexually transmitted diseases. Asian-American women were less likely than white women to report issues of sexual desire, arousal, orgasm, and dissatisfaction with sexual life although there was a slightly higher rate of concern about vaginal penetration (Nusbaum et al, 2005).

The Boston Area Community Health Study reported a lower odds ratio for sexual issues in women of black race compared to Latino and white women (Rosen et al, 2009a). A study of low-income breast cancer survivors indicated that Latino women had higher prevalence of a variety of sexual concerns (low desire, low arousal, lack of satisfaction, difficulty with orgasm) compared to Caucasian women even after controlling for covariables (Christie et al, 2010).

Physiologic differences may exist between racial/ethnic groups; these may be driven by genetics, cultural factors, and physical factors (Ravel et al, 2011). For example, serum T tends to be lower in women of African and Latino backgrounds relative to Caucasians and East Asians (Randolph et al, 2003). Whether these differences are clinically meaningful is fertile ground for future research.

Women Who Have Sex with Women and Transgender Persons

Between 1% and 2% and between 1% and 4% of women in the United States identify as lesbian or bisexual, respectively (Aaron et al, 2003; Conron et al, 2010; Herbenick et al, 2010b). Transgender persons account for 1% or less of the population but are increasingly visible in Western nations. Transgender persons include

female to male (FtM or “transmen”), male to female (MtF or “transwomen”), and individuals who elect not to categorize themselves into a gender category. A person may identify as transgender without using cross-gender hormonal replacement or having gender reassignment surgery (Persson, 2009).

A provider who is not generally familiar with women who have sex with women (WSW) and transgender persons should take time to develop rapport and ask respectful questions to elucidate fully the precise nature of sexual concerns. Tactful questions and avoidance of assumptions about sexual proclivity are essential. The majority of patients will respond well to questions for clarification if such questions are asked in a respectful and non-judgmental fashion (Stott, 2013). Care must be individualized to the patient's gender identity, sexual orientation, and sexual concerns (Wierckx et al, 2014).

Additional information on WSW and transgender persons is available on the Expert Consult website. 

Disabled Women

Disabilities are mental and/or physical impairments (congenital or acquired) that limit an individual's capacity to function independently. Physical disabilities such as chronic pain, back injury, arthritis, spinal cord injury, multiple sclerosis (MS), cerebrovascular injury, amputations, and/or metabolic diseases may make sexual activity difficult or uncomfortable (Basson et al, 2010a). However, many persons with even severe disabilities are able to adapt their sexual lives and practices to obtain a satisfying expression of their sexuality. Providers should not assume that disabled persons cannot or should not enjoy a healthy sexual life (Tepper et al, 2001; Kreuter et al, 2011).

CNS injury or lesion can be particularly damaging to sexuality. Women with lesions of the spinal cord often report diminished genital sensation, loss of sexual self-esteem, difficulty with orgasm, and dissatisfaction with sexual responses (Tepper et al, 2001). Interestingly, genital sensation is preserved in some women with spinal cord injury. This appears to be mediated by vagus nerve fibers that bypass the spinal cord and project to the nucleus tractus solitarius region of the medulla oblongata (Komisaruk et al, 2004).

The issue of sexual activity in mentally disabled persons is an ethically and legally challenging issue (Appel, 2010). Respect for human rights warrants that a person with mental disability should not be denied the right to sexual pleasure (Greenspan, 2002); at the same time, issues of consent and coercion are difficult to resolve in persons with cognitive impairments (Spiecker and Steutel, 2002). Careful consideration and ethics consultation should be considered when such cases arise (Kennedy, 2003).

Victims of Sexual Violence

The lifetime prevalence of rape (forcible sexual penetration) or attempted rape in American women is estimated at 18% (Black et al, 2011). Data from other regions of the world suggest about 1 in 3 women globally will experience intimate partner violence or sexual violence perpetrated by a nonpartner (World Health Organization, 2013). The prevalence of sexual abuse/violence against women underscores the importance of provider education on addressing sexuality in survivors.

Sexual dysfunction is a common consequence of sexual violence and/or coercion (Nusbaum et al, 2005). Physical trauma to the genitals may predispose to pain from injury or muscle dysfunction (Postma et al, 2013). More relevant for the majority of cases is the psychological toll of having been forced into unwanted sexual contact. Multidisciplinary management is recommended; the primary goals of therapy are to empower the woman to feel in control of her sexuality and to dissociate consensual sexual activity from traumatic experiences (Basson et al, 2010b; Daglieri and Andelloux, 2013).

Female genital cutting is a special case of sexual violence that is addressed on the Expert Consult website. 

The percentage of women who report sexual contact with another woman is higher in contemporary series compared to historical data (Chandra et al, 2011; Mercer et al, 2013). In a study of almost 6000 women aged 18 to 44 from the United Kingdom, 14% stated that they had experienced sexual activity with another woman (Burri et al, 2012). Data from the National Social Life, Health, and Aging study indicated a 4%, 7%, and 3% rate of lifetime same-gender sexual activity in women aged 57 to 65, 65 to 74, and 75 to 85, respectively (Waite et al, 2009). A 2010 study in American women indicated that 7% of women aged 18 to 59 had engaged in sexual activity with a female partner with a higher prevalence in the younger age groups (Xu et al, 2010). Reasons for engaging in same-gender sexual activity in these women may include curiosity, attraction to a particular individual, or restriction of contact with partners of the preferred gender (e.g., incarceration in a women's prison). About 50% of women with previous same-sex sexual experience identify as heterosexual (Xu et al, 2010). Interestingly, the converse situation is also true in that many lesbian-identified women have a historical or current history of sexual activity with male partners (Diamant et al, 1999). The behavioral term *women who have sex with women* (WSW) is often applied in contemporary research.

It is hypothesized that women are more likely than men to report flexibility in sexual attraction and behavior (Baumeister, 2000). This hypothesis is supported by increased likelihood of change in professed orientation as time passes (Diamond, 2000; Kinnish et al, 2005) and nonorientation-congruent sexual behavior in women compared to men (Rust, 1992; Baumeister, 2000). The central role of social and emotional factors in mediating many aspects of female sexual response is one hypothesis as to why/how women may experience greater flexibility in sexual attraction (Diamond, 2003). Lack of specificity in genital response may also explain arousal in response to erotic stimuli not necessarily congruent with professed orientation in women (Laan et al, 1995; Chivers and Bailey, 2005; Chivers et al, 2007). These responses could motivate some women to explore same-sex sexual activity.

Functional MRI studies have elucidated interesting differences in brain activation between heterosexual and lesbian women; there appears to be some degree of congruence between lesbian women and heterosexual men with respect to the activation of the dorso-medial area and PVN during sexual arousal (Berglund et al, 2006). This situation differs from what is observed with sexual arousal in heterosexual women, in whom activation of the MPOA and ventromedial hypothalamus is observed with sexual arousal (Savic et al, 2001). There also appear to be differences in connections to and from the amygdala between heterosexual and lesbian women (Savic and Lindstrom, 2008).

The genital physiology of sexual response is similar between WSW and non-WSW females. Common sexual activities in WSW include kissing, whole body contact, breast stimulation, stimulation of the genitals by hand, vaginal penetration with fingers or sexual toys, cunnilingus, and tribadism (genital to genital contact)

(Schick et al, 2012). Compared to their non-WSW peers there is some evidence that WSW have a greater diversity of sexual experiences (Burri et al, 2012) and are more likely to engage in bondage and domination/sadomasochism (BDSM) or to have consensually nonmonogamous relationships (Richters et al, 2008).

Studies on the prevalence of sexual dysfunction in WSW are scant. Tracy et al reported on the validation of the FSFI for use in a lesbian population (Tracy and Junginger, 2007). In an Internet study, Shindel et al reported on a population of 1566 WSW. Using a modified version of the FSFI it was estimated that 25% of respondents were at risk of sexual dysfunction based on previously validated cutoffs for the total FSFI score in non-WSW females. The FSFI cutoff showed reasonable correlation to the single-item FSFI question on sexual satisfaction. Risk factors for high risk of sexual dysfunction in these women included overactive bladder symptoms, lower sex frequency, and nulligravidity (Shindel et al, 2012).

Attention to the unique health care needs of WSW and transgender persons is a priority. The urologist may be called on to address sexual wellness issues in transgender persons as part of comprehensive urology care. Many transgender persons report a history of discrimination from both the general public and from health care providers, so it is critically important to establish sensitive rapport early when interacting with transgender patients (Makadon, 2011). Lesbian and bisexual women are also at greater risk of poor health. Numerous studies have indicated a higher rate of unhealthy behaviors in WSW and transgender persons, including obesity and tobacco use. Safer sex practices may not be widely used by WSW (Schick et al, 2012; Kerr et al, 2013). A 2013 study reported that 62% of WSW do not use a barrier for sexual toys, between 83% and 87% do not use a barrier for cunnilingus, and 88% have never used barriers for manual stimulation of the genitalia. In the 316 women from this study with more than one partner, 57% sometimes or never used barriers (Rowen et al, 2013).

Low adherence to safer sex practices and gynecologic cancer screening may result in part from the absence of concern about conception and a common misperception (all too often shared by health care providers) that STIs are not likely to be transmissible between women (Matthews et al, 2004). WSW are at risk of human papillomavirus (HPV) infection by transfer of vaginal fluids between female partners and also by sexual contact with men (Koh et al, 2005). Male sexual partners of WSW are more likely to be at risk for human immunodeficiency virus (HIV) and HPV infection. Between 13% and 17% of WSW report a history of STI; indeed, Singh and colleagues (2011) reported that the rate of chlamydia infection in WSW was slightly higher than the prevalence in women who have sex exclusively with men (7% vs. 5%, respectively). STI including HPV may be transmitted between female partners directly or by sexual toys or by intercourse with male partners. The prevalence of HIV infection appears to be higher in lesbians versus heterosexual women. Education on safer sex practices should be a part of sexual health consultation in WSW (Diamant et al, 1999; Matthews et al, 2004; Marrazzo et al, 2005).

Special mention is warranted regarding women who have been victims of female genital cutting (FGC). FGC is a nonspecific term encompassing a wide variety of cultural practices performed on the genitals of girls and young women, ranging from removal of the clitoral prepuce to removal of the clitoris and resection of sewing together of the labia majora (infibulation), leaving a small aperture for passage of menstrual fluids ([World Health Organization, 2008](#)). FGC is classified by the World Health Organization on a three-point scale ([World Health Organization, 2008](#)):

1. Partial or total removal of the clitoris and/or prepuce
2. Partial or total removal of the clitoris and the labia minora
3. Infibulation; narrowing of the vaginal orifice by suturing of the labia majora with or without clitoral removal

FGC is most prevalent in portions of East Africa including Egypt ([World Health Organization, 2008](#)). It is estimated that as many as 120 million women and girls have been subjected to FGC ([Elchalal et al, 1999](#)). This practice may be carried out in a variety of settings, from surgical suites using sterile technique or in traditional village ceremonies using crude instruments from the environment. While the practice is most common in Islamic cultures it is not an Islamic mandate and most proponents do not explicitly link the practice to religious requirements ([Shafer and Shafer, 2013](#)).

Dyspareunia is common in women who have had FGC. In addition to physical concerns survivors of FGC may have substantial post-traumatic stress disorder and/or cultural beliefs on sexuality that will interfere with their ability to enjoy sexual activity. Women who have undergone FGC have lower levels of sexual functioning in comparison to women from similar cultural backgrounds who have not undergone FGC ([Andersson et al, 2012](#)). The degree of sexual impairment in FGC survivors is variable and dependent in large part on the degree of tissue manipulation; as would be expected women with type III FGC are most likely to have impaired sexual response ([Andersson et al, 2012](#)).

Sensitivity to these issues is critical in the care of these patients; referral to specialists with particular expertise in addressing the needs of women who have undergone FGC is warranted and may yield benefit for the patient ([Fazari et al, 2013](#)). Some women who have undergone FGC support the practice and are content with their genital appearance/function (Johnson, personal communication). Although one need not be supportive nor tolerant of the practice of FGC, the preferences of adult women who have undergone FGC should be respected as they pertain to their own personal sexual life and experience.

Women with Urologic Concerns

Overactive bladder, stress urinary incontinence, and incontinence with sexual activity have been identified as independent risk factors for FSD in numerous studies (Rosen et al, 2009b; Wehbe et al, 2010). The prevalence of sexual dysfunction and/or decreased sexual activity in women with lower urinary tract symptoms varies between 19% and 50% depending on population and means of assessment. Women with urinary issues are twice as likely to report disruption of sexual life compared to their peers (Chen et al, 2013). Painful bladder syndromes and interstitial cystitis have also been linked to impairment of sexual response, sexual avoidance, and sexual pain in up to 88% of affected women (Bogart et al, 2011; Gardella et al, 2011).

Management of overactive bladder and/or stress incontinence has been clearly linked to positive changes in sexual response for women (Rogers et al, 2008; Wehbe et al, 2010). However, placement of transvaginal mesh for pelvic organ prolapse or stress incontinence may contribute to dyspareunia, alteration of vaginal lubrication, and/or discomfort for sexual partners (Helstrom and Nilsson, 2005; Boyles and McCrery, 2008). Procedures that involve placement of slings may disrupt neurovascular innervations to the genital organs (Benson and McClellan, 1993). While the risks of pelvic surgery for prolapse and/or incontinence are real several studies have reported improvements in sexual function after mesh placement; in many cases improvement is driven by resolution of incontinence and/or prolapse-related sexual dysfunction (Roovers et al, 2006; Altman et al, 2009).

Gynecologic Surgery Patients

The effects of hysterectomy on sexual function are mediated in large part by the indication for the procedure (Roovers et al, 2003); women who experience sexual dysfunction from gynecologic conditions (e.g., leiomyoma, endometriosis, etc.) (Helstrom, 1994; Grimes, 1999) are more likely to benefit from surgery whereas those without sexual issues at baseline may experience worsening of sexual function (Dennerstein et al, 1977; Carlson, 1997).

Cancer Patients

Sexual issues are common in women after pelvic cancer surgeries such as cystectomy/urethrectomy, vulvectomy, colectomy, abdominoperineal resection, and proctectomy (Raina et al, 2007; Donovan et al, 2010; Philip et al, 2013). Sexual dysfunction is also a risk of pelvic radiotherapy as a primary or adjuvant treatment (Incrocci and Jensen, 2013). Disruption of pelvic neurovasculature, side effects of treatment, and body image issues may predispose to impairment of sexual responses and pain (Raina et al, 2007).

In cystectomy and/or urethrectomy the anterior vaginal wall may be partially resected or otherwise compromised, leading to difficulty with vaginal penetration (Yang et al, 2006). Disruption of the nerve innervation to the external genitalia, vagina and clitoris is a common risk during cystectomy/urethrectomy (Stenzl et al, 1995). A 2004 study indicated that difficulty with orgasm, desire, and arousal are very common in women after radical cystectomy. Slightly less than half of female cystectomy patients engage in coital intercourse after cystectomy and slightly over half report a decline in sexual life satisfaction (Zippe et al, 2004).

Issues in cancer survivorship are discussed in more detail on the Expert Consult website.

KEY POINTS: SPECIAL POPULATIONS

- A woman's sexuality may be affected by medical, sociocultural, and life factors.
- Sensitivity to the sexual wellness needs of minority populations and/or women who have suffered trauma is an essential component of professionalism.

FEMALE SEXUAL DYSFUNCTION

Semantics and Controversy

Female sexual dysfunction (FSD) is an umbrella term that encompasses distressing situations that interfere with a woman's ability to enjoy a satisfying sexual life. FSD is not truly a diagnosis but rather an umbrella term that may encompass one or more distressing situations that interfere with a woman's ability to enjoy a satisfying sexual life.

Controversies regarding FSD are addressed on the Expert Consult website.

Epidemiology

There is marked variability in the prevalence of sexual issues between regions (Laumann et al, 2006). Prevalence of sexual issues in the general female population is ambiguous due to selection bias, limited data collection, and variation/disagreement about what constitutes a sexual problem. Studies on the prevalence of FSD are presented in Table 32-1.

Disruption of sexual response and sexuality-related distress may occur independently. In a U.K. study of female twins only 37% of women with sexual dysfunction (assessed by Female Sexual Function Index [FSFI]) had concomitant sexual distress (assessed by the Female Sexual Distress Scale [FSDS]) (Burri et al, 2011). It is also important to note that not every sexually distressing situation is a sexual dysfunction; a woman may have distress about sexuality that is related to interpersonal issues rather than a disturbance in her own sexual response. The same twin study from the United Kingdom demonstrated that up to 16% of women who had "normal" sexual function per the FSFI still reported significant sexual distress. In cases of sexual distress without sexual dysfunction, interpersonal and/or psychological issues (Burri et al, 2011) were the principal bothersome issues. In a study of over 31,000 women in the United States, 43% of women had a sexual concern but just 22% endorsed sexual distress; just 12% had a sexual problem and distress (Shifren et al, 2008). A similar Finnish study reported a 34% prevalence of FSD, 36% prevalence of sexual distress, and a 20% prevalence of concomitant sexual dysfunction and distress (Witting et al, 2008).

Due to ambiguity in terminology, Raina et al (2007) have suggested a tripartite classification system:

1. *Sexual complaints* are expressions of discontent associated with sexual function. Women with sexual complaints are likely to have issues related to their partner and/or their personal experience of sexuality. Education on the anatomy and physiology of sexual response as well as communication and interpersonal skills may be sufficient to resolve many sexual complaints.
2. *Sexual dysfunction* is a disturbance in one more or more phases of the sexual response cycle and/or pain during sexual activity. Women with sexual dysfunction may compensate for it in some fashion and thus preserve a sense of sexual satisfaction or at least contentment.
3. *Sexual disorder* is the combination of sexual dysfunction and personal distress relating to the sexual dysfunction. These women merit complete evaluation to assess for etiology and treatment options.

Whether one adheres to this classification scheme or not, it is always important when evaluating research or seeing a patient to gauge personal distress as this is a very important determinant of which treatments are indicated/desired.

Sexual dysfunction is more frequent in older women; *sexual complaints* may be more frequent in younger women (Roos et al, 2012). Similarly, distress related to sexual issues appears to be higher in premenopausal versus menopausal women (Berra et al, 2010); this may be due in part to adaptation on the part of some older women. The highest prevalence of sexual concerns with attendant distress is in women aged 45-64 (Shifren et al, 2008). It is reasonable to hypothesize that this is an age group in whom sexual activity remains a priority despite physical changes of menopause and advancing age, which may compromise sexual response. Distress is

Cancers of nongenital sites may influence sexual function due to alteration in body image, genital and systemic side effects of chemotherapy and radiation, and/or psychological distress ([Perez et al, 2009](#)). Particular interest has been dedicated to sexuality and breast cancer survivorship; breast cancer survivors may be treated with estrogen-blocking drugs that may cause genital atrophy and premature symptoms of menopause. Psychosocial issues are also of great importance in breast cancer patients due to the sexual context

of the female breast in many cultures ([Schover, 1991](#); [Bredart et al, 2011](#); [Kedde et al, 2013](#)).

In recent years concern for quality of life and cancer survivorship have increased interest in promoting sexual wellness for cancer survivors ([Raina et al, 2007](#); [Perez et al, 2009](#)). Oncologists of all disciplines should prioritize sexual quality of life as part of their patient's overall holistic treatment plan.

Some critics have contended that constructs of FSD are derived too heavily from “male” models of sexual response; such proponents may be supportive of the concept of FSD but concerned that the paradigms mediating contemporary concepts of FSD are flawed and can be improved upon (Basson, 2002). Others have contended that FSD is mediated by emotional, mental, or social factors and that these issues are of greater relevance to sexual function than biomedical issues (Tiefer et al, 2002; Tiefer, 2007). Bancroft and colleagues (2003) demonstrated that the best overall predictors of sexual distress in women were emotional relationship with partner and general well-being. Physical issues also played a role but these effects were relatively minor (Bancroft et al, 2003). The most concerning allegations against the concept of FSD are that it does not reflect women’s experience of sex and/or is a “medicalization” of female sexual response for the purpose of financial gain (Tiefer, 2002; Moynihan, 2004).

It is legitimate to challenge current concepts in human sexuality with novel ideas. Similarly, it is prudent to be concerned about the

potential victimization of women and their partners for financial gain (Bancroft, 2002). However, sexuality is a biologic process and medical issues may interfere with a woman’s capacity to enjoy her sexuality (Basson and Leblum, 2003). In the ideal future, optimization of a given woman’s sexual health will be tailored to her unique preferences and needs and will include biomedical, psychological, and/or interpersonal interventions as indicated (Basson et al, 2010b).

As physicians are in the best position to understand the physical (and in some cases mental) processes of sexual response, involvement of the medical community in optimization of sexual wellness is of critical importance for many women. Individual providers will best serve their patients by integrating medical assessment and therapies (when appropriate) with psychosocial intervention in a holistic approach that recognizes the rich complexity of human sexual response (Althof, 2011).

TABLE 32-1 Epidemiology of Female Sexual Dysfunction (FSD) in General Populations

STUDY	REGION	POPULATION	FSD DEFINITION	FSD PREVALENCE	NOTES
Laumann et al, 1999	USA	1749 women aged 18-59	Yes on ≥ 1 PRO	43%	
Oksuz and Malhan, 2006	Turkey	518 women aged 18-55	FSFI ≤ 25	48%	
Nicolosi et al, 2005	Asia	3350 women aged 40-80	Sometimes or occasionally experiencing >1 PRO	32% to 82%	Lack of interest most common
Nicolosi et al, 2006b	Anglophone Countries	3006 women aged 40-80	Sometimes or occasionally experiencing >1 PRO	28% to 57%	Lack of interest most common
Nicolosi et al, 2006a	Europe	5023 women aged 40-80	Sometimes or occasionally experiencing >1 PRO	23% to 46%	Lack of interest most common
West et al, 2008	USA	1944 women aged 30-70	PFSF ≥ 40 = low desire PFSF* < 40 + PDS† ≥ 60 = HSDD	Low desire 36%; HSDD 8%	Assessment of sexual desire only
Valadares et al, 2008	Brazil	315 women aged 40-65 with 11+ years of school	PEQ score ≤ 7	36%	
Shifren et al, 2008	USA	31,581 women aged 18+	CSFQ response of “never” or “rarely”	43%	Sexual distress was 22% with combined distress and FSD in 12%
Witting et al, 2008	Finland	6601 women aged 18-33	FSFI < 26.55	35%	
Chedraui et al, 2009	Ecuador	409 women aged 40-59	FSFI < 26.55	56%	Lubrication and pain domains were lowest
Rosen et al, 2009b	USA	3202 women aged 30-79	FSFI < 26.55	40%	Only 51% sexually active in past 4 wk
Blumel et al, 2009	Latin America	7243 women aged 40-59	FSFI < 26.55	57%	74% sexually active
Ishak et al, 2010	Malaysia	163 women aged 18-65	Malaysian FSFI ≤ 55	26%	
Echeverry et al, 2010	Colombia	410 women aged 18-40	FSFI < 26.5	30%	
Shindel et al, 2011	USA	1241 women aged 25 ± 3	FSFI < 26.55	50%	
Mezones-Holguin et al, 2011	Peru	335 women aged 40-59	FSFI < 26.5	35%	
Shindel et al, 2012	North America	1566 WSW aged 18-86	Modified FSFI < 26.55	25%	
Moghassemi et al, 2011	Iran	149 women aged 43-64	FSFI < 26.5	87%	
Zhang and Yip, 2012	Hong Kong	1410 women aged 19-49	Face-to-face interview using DSM-IV-TR criteria	38%

CSFQ, Changes in Sexual Functioning Questionnaire; DSM-IV-TR, *Diagnostic and statistical manual for mental disorders*, fourth edition, text revision; FSFI, female sexual function index; HSDD, hypoactive sexual desire disorder; PDS, personal distress scale; PEQ, personal experiences questionnaire; PFSF, profile of female sexual function; PRO, patient reported outcomes; WSW, women who have sex with women.

TABLE 32-2 Prevalence and Definition of Female Sexual Dysfunctions

	PREVALENCE*	DEFINITION†
Hypoactive sexual desire/low libido	9%-60%	Diminished feelings of sexual interest or desire, absence of sexual thoughts, and/or lack of receptivity to sexual activity‡
Sexual arousal disorder/sex not pleasurable	5%-51%	Genital Female Sexual Arousal Disorder: Disruption of clitoral erection, vaginal vasocongestion, vaginal lubrication
Difficulty with genital lubrication	8%-60%	Psychological Female Sexual Arousal Disorder: Absent or markedly diminished feelings of excitement or pleasure in response to sexual stimuli
Persistent genital arousal disorder	~1%	Mixed Female Sexual Arousal Disorder: GFSAD and PFSAD
Female orgasmic disorder	7%-65%	Persistent, recurrent, intrusive, and/or distressing sensations of genital arousal not related to sexual stimulation and that do not resolve after orgasm
Sexual pain disorders	4%-42%	Lack of experience of orgasm or diminished orgasm intensity despite high sexual arousal after a period of sufficient sexual stimulation and arousal
		Dyspareunia: Persistent/recurrent pain with attempted/complete vaginal entry with a penis, finger, or other object
		Vaginismus: as vaginal spasm or pain in response to penetration with a penis, finger, or other object despite a desire for penetration to occur‡
Anxiety about sexual performance	6%-16%	N/A

*Laumann et al, 1999; Nicolosi et al, 2005, 2006a, 2006b; Shifren et al, 2008; West et al, 2008; Witting et al, 2008; Garvey et al, 2009.

†Waldinger et al, 2009; Basson et al, 2010b.

‡The term *vaginismus* is no longer preferred, as it includes significant semantic baggage as a psychological disorder.

also more frequent in women who are partnered; a woman who is unpartnered may not be concerned with sexuality and will not have bother stemming from being unable to satisfy her partner.

FSD has been linked to increasing age (Hisasue et al, 2005; Ponholzer et al, 2005; Oksuz and Malhan, 2006; Valadares et al, 2008; Blumel et al, 2009; Chedraui et al, 2009), menopausal symptoms (Oksuz and Malhan, 2006; Valadares et al, 2008; West et al, 2008; Chedraui et al, 2009; Nappi and Lachowsky, 2009), absence of partner (Valadares et al, 2008), age of partner (Chedraui et al, 2009), partner sexual dysfunction (Hisasue et al, 2005; Blumel et al, 2009; Chevret-Measson et al, 2009; Zhang and Yip, 2012), marital discord (Zhang and Yip, 2012), urinary incontinence (Rosen et al, 2009b; Kim et al, 2011), urinary symptoms (Blumel et al, 2009; Rosen et al, 2009b; Mezones-Holguin et al, 2011; Shindel et al, 2012), depression (West et al, 2008; Rosen et al, 2009b; Echeverry et al, 2010), tobacco use (Oksuz and Malhan, 2006; Roos et al, 2012), sedentary lifestyle (Esposito et al, 2010), infertility (Millheiser et al, 2010), HIV infection (Wilson et al, 2010), hypothyroidism (Atis et al, 2010), diabetes (Giraldi and Kristensen, 2010), sleep apnea (Subramanian et al, 2010), and poor general health (Valadares et al, 2008; Blumel et al, 2009; Ishak et al, 2010; Navaneethan et al, 2010).

Several factors have conflicting data on association with FSD. Estrogen replacement has been linked to both better (Chedraui et al, 2009) and worse (Blumel et al, 2009) sexual function in postmenopausal women. Similarly, both higher (Chedraui et al, 2009) and lower (Blumel et al, 2009; Echeverry et al, 2010) educational achievement have been linked to risk of FSD. Conflicting data have been reported on the role of obesity in FSD. Some studies have reported lower rates of sexual activity and sexual desire (Smith et al, 2012) in obese women and in women with metabolic syndrome (Martelli et al, 2012); however other studies (Christensen et al, 2011) have suggested that among women who are sexually active, obesity (Christensen et al, 2011) and metabolic syndrome (Kim et al, 2011) are not linked to sexual dysfunction. Although data are ambiguous, concern for general health dictates that practitioners should encourage patients to maintain healthy body weight (Goldstein and Alexander, 2005).

Classification

Linear sexual response cycles have served as the foundation for most modern classification systems for FSD (Masters and Johnson, 1966).

While the linear model may not perfectly reflect sexual response in every woman it does represent a convenient means to organize diagnostic criteria. A summary of specific female sexual issues and their estimated prevalence is presented in Table 32-2. There is substantial comorbidity between sexual issues in women (Giles and McCabe, 2009).

The fifth edition of the *Diagnostic and Statistical Manual for Mental Disorders* (DSM-5) incorporated several changes to diagnostic criteria for FSD. DSM-5 emphasizes that FSD should be categorized as lifelong versus acquired and generalized versus situational. Duration of at least 6 months is required to apply a diagnosis except in the case of medication-induced sexual dysfunction.

In the DSM-5 sexual desire and arousal disorders in women have been combined into “female sexual interest/arousal disorder.” This change was to address concerns that active sexual desire is not present in all sexually healthy women (Basson, 2002) and that some women do not differentiate sexual arousal from desire (Graham et al, 2004; Brotto et al, 2009). Similarly, the DSM-IV terms “vaginismus” and “dyspareunia” have been combined into “genito-pelvic pain/penetration disorder” in DSM-5. These reorganizations were controversial (Derogatis et al, 2010).

There has been scant research using these new diagnoses; in the interest of simplicity we will outline this chapter according to previous diagnostic categories (Basson et al, 2004).

KEY POINTS: FEMALE SEXUAL DYSFUNCTION

- FSD is a controversial topic but one of great importance to many women.
- A variety of medical and psychosocial issues have been clearly linked to risk of sexual concerns in women.
- Classification of female sexual disorders remains controversial; however, most classification schemes recognize disorders of sexual desire/interest, arousal, orgasm, and sexual pain.

HYPOACTIVE SEXUAL DESIRE DISORDER

Etiology

There are numerous causes for low sexual desire in women. Hubin and colleagues (2011) proposed five axes relevant to hypoactive

TABLE 32-3 Risk Factors for Hypoactive Sexual Desire Disorder

Cognitive	Lack of knowledge, negative anticipation, distractions, negative body image, depression
Physiologic	Neurologic, hormonal, surgical, iatrogenic, age
Behavioral	Avoidance, detachment linked to routine, habituation to infrequent sex
Emotional	Guilt, anxiety, insecurity, conflict
Environmental	Work/family obligations, poor communication, decreased attraction, societal influence

Modified from Hubin A, De Sutter P, Reynaert C. Etiological factors in female hypoactive sexual desire disorder sexologies. 2011;20:149–57.

sexual desire disorder (HSDD): cognitive, physiologic, behavioral, emotional, and environmental (Table 32-3). Women who do not experience desire at baseline but who respond to sexual initiation and are not distressed do not meet criteria for HSDD (Basson, 2002).

It is important to clarify that many early studies characterized sexual desire in terms of spontaneous sexual interest and desire. There is increasing evidence that for many women absence of sexual desire may be typical and not associated with distress. This relationship may be compounded by the self-attribution theory, which articulates that individuals may determine personal beliefs based on their personal behaviors rather than vice versa. For example, a woman who does not think about or initiate sex but who is receptive to sexual stimuli and enjoys sexual activity may (mistakenly) conclude that she is not interested in sex (Eccles and Wigfield, 2002).

Events or issues that occurred prior to onset of decreased sexual desire should be assessed. Common precipitating factors include hormonal changes, medication use, changes in relationship status, or life stressors (Brotto et al, 2010). It is very common for women to experience a reactive decline in sexual desire in the presence of other impediments to sexual activity. It may also be helpful to elucidate whether the decline in sexual interest is mental, emotional, or both. A subtle but important distinction may exist between absence of visceral desire for sex (nonspecific and colloquially referred to as “being horny”) and absence of intellectual interest in sexual pleasure/intimacy (which may be related to psychosocial and partner issues). Patients may not be able to differentiate but this inquiry could provide valuable insights.

Hypoestrogenism has been clearly linked to decreased sexual desire in women, primarily in association with menopause. Women who are surgically menopausal report more severe perturbation of sexual desire relative to nonmenopausal women (de Almeida et al, 2011) and naturally menopausal women (West et al, 2008). Androgen deficiency has also been linked to decreased sexual interest in women (Warnock et al, 1997).

Psychosocial stressors have a marked effect on sexual interest in women. Depression is prevalent and includes a well-known association with HSDD. The HSDD Registry for women reported that up to one third of women with HSDD also report clinically significant depressive symptoms (Clayton et al, 2012). Sexual interest also declines with increasing relationship duration and/or with partner conflict (Segraves, 2002). Interestingly, although aging is associated with declines in sexual desire, associated distress may also decrease; this may account for the relatively lower rate of HSDD in older women compared to younger women (West et al, 2008).

The use of medications, particularly antidepressants of the SSRI class, is associated with HSDD (Montejo et al, 2001; Clayton et al, 2006). Other classes of medication commonly associated with HSDD in women are presented in Box 32-1; virtually every

BOX 32-1 Medications Associated with Female Sexual Dysfunction

Antiandrogens
 Spironolactone
 LHRH agonists
 Anticonvulsants
 Anticholinergics
 Antidepressants
 Antiestrogens
 Tamoxifen
 Raloxifene
 LHRH agonists
 Antihistamines
 Antihypertensives
 Diuretics
 β -blockers
 Calcium channel blockers
 Chemotherapy
 Cyclophosphamide
 Corticosteroids
 Hormones
 Contraceptives
 GnRH agonists
 Metoclopramide
 Metronidazole
 Recreational drugs
 Alcohol
 Amphetamines
 GnRH, gonadotropin-releasing hormone; LHRH, luteinizing hormone-releasing hormone.

medicine has at least anecdotally been linked to a risk for sexual problems.

Treatment

At the time of this writing, there is no approved pharmacotherapy for HSDD in women. Attention to psychosocial issues and partner variables is of critical import. Stress reduction strategies, maintenance of general health, and addressing relationship issues are generally regarded as positive interventions, although empiric studies are scant.

Sexual interest can be an end unto itself and sexual desire can be positively perceived even in the absence of sexual activity (Wallen and Lloyd, 2011). This finding argues against the regulatory agency mandate that the end point of greatest interest in the treatment of HSDD is “satisfying sexual events” (Derogatis et al, 2011). Many women endorse satisfaction from sexual desire or a “desire to be desired”; this does not require a sexual encounter (satisfying or otherwise) to yield benefit (Meana, 2010; Bancroft and Graham, 2011). These topics remain controversial and speak to the need for more focused qualitative research on the fundamental underpinnings of women’s sexual function.

Psychosexual Therapy

There are numerous mental health approaches to addressing HSDD in women. The general goals of therapy include education on sexual physiology and response, determination of type and frequency of sexual activity that is personally desired, and developing interpersonal communication skills (Kingsberg and Althof, 2009; Althof, 2010).

Cessation/Modulation of Medical Therapy

The ideal resolution of sexual problems related to a medication is cessation or substitution with a less side-effect-prone medication that produces similar effects. This is a preferred management strategy for SSRI-associated sexual dysfunction. Alternative strategies include “drug holidays,” decreased dosages, and alternative agents acting as replacements or adjuncts (Ahrold and Meston, 2009; Fabre et al, 2011; Clayton et al, 2013; Taylor et al, 2013).

A meta-analysis of adjunctive treatments for SSRI-induced sexual dysfunction confirmed that twice-daily dosing with bupropion 150 mg improved sexual function outcomes; benefit was not realized with a single daily dose (Taylor et al, 2013). The 5-HT_{1A} partial agonist buspirone (20 to 60 mg/day) has also shown superior efficacy compared to placebo (50% remission for buspirone vs. 20% for placebo) for the management of sexual symptoms in women taking an SSRI for major depression (Landen et al, 1999). A randomized study of women taking SSRIs for depressive symptoms indicated that on-demand use of sildenafil (50 to 100 mg on demand) enhanced orgasmic function relative to placebo (Nurnberg et al, 2008).

Estrogens

E plays an important role in sexual desire for women (Nappi and Polatti, 2009). Correction of E deficiency has been associated with improvement in female sexual function, including desire (Gast et al, 2009; Nastri et al, 2013). This may occur by direct action on libido or by improvement in sexual arousal response and reduction in genital pain resulting from vulvovaginal atrophy.

Androgens

Supplementation with T increases sexual desire in women with low libido and low serum androgen levels (Lobo et al, 2003; North American Menopause Society, 2005). Studies on androgen for the management of HSDD in women are presented in Table 32-4. T has also been shown to improve other aspects of sexual function such as orgasm, pleasure concerns, responsiveness, and self-image (Davis et al, 2006; Shifren et al, 2006; Davis et al, 2008a, 2008b). Although most studies have investigated T as an adjunct to estrogen (in premenopausal women or in postmenopausal women already taking an estrogen supplement), a number have also investigated T monotherapy and have shown similar benefit with respect to sexual interest, desire, and sexual events (Davis et al, 2008b). T supplementation may work in part by increasing general markers for quality of life such as feelings of health, energy, and sense of well-being (Shifren et al, 2000). Mood and affect are crucially important in sexual response, and enhancement of these parameters may be of great benefit (Middleton et al, 2008).

A T patch was approved in Europe as a treatment for HSDD in women; the product was subsequently withdrawn (European Medicines Agency, 2012). The T-patch treatment did not achieve approval in the United States because of concerns about long-term safety and a perceived lack of clarity regarding the concept of female androgen insufficiency. Currently there is no approved androgen-based treatment for sexual-interest disorders in women in the United States (Wierman et al, 2006). Off-label T is used in women by some clinicians (Bachmann et al, 2002; Goldstein and Alexander, 2005).

Use of tibolone, flibanserin, bremelanotide, and other drugs for HSDD is detailed on the Expert Consult website.

FEMALE SEXUAL AROUSAL DISORDER

Female sexual arousal disorder (FSAD) may refer to the disruption of genital responses (GFSAD), to psychological arousal responses (PFSAD), or mixed FGSAD and PFSAD (Basson et al, 2010b).

Etiology

Atherosclerotic lesions reduce genital blood flow and responsiveness in animal models of FSD (Park et al, 2000; Traish et al, 2010). Vascular or neurologic disease may also contribute to GFSAD (Goldstein and Berman, 1998; Traish et al, 2010). Pelvic surgery (gynecologic, urologic, or colorectal) may also perturb genital innervations (particularly the autonomic innervation of the pelvic nerve) and vascular supply (Raina et al, 2007). Nicotine is associated with impairment of genital response (Harte and Meston, 2008). Diabetes represents a special risk factor for FSD, as it may be associated with neurologic, vascular, and/or hormonal defects (Kim et al, 2009; Giraldi and Kristensen, 2010) in addition to marked psychological morbidity (Bitzer and Alder, 2009).

In addition to their known effects on sexual desire, antidepressants may also impair genital arousal responses. Animal models have demonstrated inhibition of genital vasodilation from pelvic nerve stimulation after administration of antidepressant medications including SSRIs and serotonin/norepinephrine reuptake inhibitors (Angulo et al, 2004). In this same study there was some difference within class, suggesting that effects may not be universal for all antidepressants or in all women. Furthermore, as depression itself is a risk factor for sexual dysfunction, some women may experience improvement in sexual satisfaction when treated with antidepressant drugs (Ishak et al, 2013).

The hormonal milieu may have a profound influence on genital tissues; hence endocrinopathy is an important cause of GFSAD. Perturbation of genital response (thinning of vagina, dryness, rise in pH) is often attributable to hypoestrogenism from menopause (Bachmann et al, 1999).

PFSAD typically originates from psychological causes. Common examples include dissatisfaction with a sexual partner, nonsexual stressors that reduce mental energy required for fostering of sexual interest, and depression (Basson et al, 2010b).

Evaluation of Female Sexual Arousal Disorder

Appropriate characterization of FSAD is required to determine etiology and potential avenues for intervention. A precise history is critical to this process. Time of onset and associated factors should be assessed. Attention to the woman's feelings and relationship status is also of critical import (Brotto et al, 2010).

Treatment of Female Sexual Arousal Disorder

Psychosocial

Attention to psychosocial factors mediating FSAD is always an important component of treatment. These issues may or may not be primary in causing FSAD but they will be present to some extent in virtually every case. These issues should be addressed, or appropriate referral to a therapist should be made early in treatment.

Devices

The Eros Clitoral Therapy Device (Eros-CTD) is a battery-powered vacuum-driven suction device designed to be applied to the clitoris. In a validation study it was shown to enhance sensation, arousal, and orgasmic potential in women with and without sexual concerns (Billups et al, 2001).

Outside the realm of medical devices there exists a wide variety of sexual enhancement products. Examples include vibrators/massagers, dildos, and devices used for erotic/fantasy role-play (Queen, 2013). These devices may be of great usefulness in improving sexual response. Studies have indicated that many women use and have used vibrators for sexual stimulation; vibrator use has been associated with better scores on the FSFI (Herbenick et al, 2009, 2010a). Fantasy role-play and power exchange activities such as consensual bondage/dominance/sadomasochism (BDSM) are used for sexual stimulation by small but significant numbers of women (Moser and Kleinplatz, 2006; Richters et al, 2008).

Tibolone

Tibolone is a synthetic hormone that is metabolized to several forms with estrogenic activity; tibolone also has the capacity to bind and activate ARs. Tibolone is superior to placebo in enhancing sexual desire in premenopausal women (Laan et al, 2001). In a randomized controlled study of postmenopausal women with sexual dysfunction (defined by FSFI criteria) tibolone produced greater increases in FSFI score (driven primarily by the desire, arousal, and satisfaction domains) compared to a combined estrogen/P patch. Interestingly, there was no significant difference in sex-related distress between treatment groups (Nijland et al, 2008).

Flibanserin

Flibanserin is an agonist against the 5HT_{1A} receptor and antagonist against the 5HT_{2A} receptor (D'Aquila et al, 1997). Flibanserin also exerts dopaminergic and noradrenergic action (Invernizzi et al, 2003; Gelez et al, 2013a). These CNS effects may enhance sexual interest (Stahl et al, 2011; Gelez et al, 2013b).

Flibanserin was initially investigated as a treatment for major depressive disorder. Four randomized studies of flibanserin for

depression (enrolling 523 women) did not demonstrate acceptable efficacy compared to active treatment; however, there was a slight improvement in sexual function in treated women. This improvement did not reach statistical significance although the studies were not designed/powerd to assess sexual function outcomes (Kennedy, 2010).

High doses of flibanserin (100 mg/day) are consistently associated with statistically significant positive changes in sexuality (particularly desire), whereas 50-mg doses are less consistent (Goldfischer et al, 2011; Derogatis et al, 2012; Thorp et al, 2012; Katz et al, 2013; Simon et al, 2014). There is also a slight but significant superiority of flibanserin over placebo based on patient-reported efficacy in all studies. Highlights of published trials on flibanserin are summarized in Table 32-5. Unpublished randomized controlled studies in other populations have yielded similar results.

Adverse events associated with flibanserin include somnolence, headache, vertigo, and nausea. A 52-week open-label study in 962 women reported an 11% discontinuation rate as a result of adverse events, most of which were minor in nature (Jayne et al, 2012). At the time of this writing, flibanserin has not been approved for management of FSD in the United States after being rejected by U.S. Food and Drug Administration (FDA) advisory boards in 2010 and 2013 (Lenzer, 2010).

TABLE 32-5 Randomized Controlled Trials of Flibanserin for Hypoactive Sexual Desire Disorder (HSDD)

Bremelanotide (also Known as PT-141)

Bremelanotide is an analogue of α -melanocyte-stimulating hormone (MSH) (Wikberg et al, 2000). MSH is active in the hypothalamus of female rodents and induces sexual solicitation behavior (Pfaus et al, 2004). In a placebo-controlled randomized trial, 18 premenopausal women with female sexual arousal disorder were treated with intranasal bremelanotide 20 mg. Women who received treatment reported greater levels of sexual arousal in response to sexually explicit material compared to women receiving placebo; there was no significant difference in genital arousal response (Diamond et al, 2006).

The nasal route of administration for bremelanotide has been associated with an increase in systemic blood pressure. A subcutaneous, on-demand route of administration is under investigation.

Other Medical Therapy

Several small studies have suggested beneficial changes in sexual desire in women treated with a proprietary blend of herbals and vitamins (Ito et al, 2006). Use of any herbal therapy should be approached with caution given the lack of regulation for manufacturer and efficacy claims.

TABLE 32-4 Randomized Controlled Trials of Testosterone Therapy for Hypoactive Sexual Desire Disorder (HSDD)

‡Women taking vaginal estrogens continued on stable dosing regimens.

Some sexual enhancement products are marketed as “novelty items” not actually for use in sexual contexts to limit manufacturer liability for potential injuries. Urologists need not be experts in such devices but should advise patients to use reasonable cautions to prevent trauma (e.g., laceration, electric shock, numbness, loss inside a body cavity, etc.) (Aaronson and Shindel, 2010).

Oral Pharmacotherapy

PDE5I have been of great interest in treating FSAD because of the similarities in the mechanisms of vascular engorgement between men and women (Kim et al, 2003; Munarriz et al, 2003). Taken in aggregate, the data are conflicting on the efficacy of sildenafil (50 to 100 mg) for FSAD (Chivers and Rosen, 2010). The greatest efficacy of these drugs has been demonstrated in women with clearly defined etiologies for impairment of genital response, typically

neurologic lesions such as spinal cord injury, MS, or diabetes (Sipski et al, 2000; Dasgupta et al, 2004; Caruso et al, 2006). PDE5 inhibitors are not approved for use in women and hence any use of these drugs in women is off label.

Details on apomorphine, transdermal agents, lubricants, and hormones are detailed on the Expert Consult website.

PERSISTENT GENITAL AROUSAL DISORDER

Persistent genital arousal disorder (PGAD) is persistent, recurrent, intrusive, and/or distressing sensations of genital arousal that are not related to sexual stimulation and that do not resolve after orgasm (Basson et al, 2010b). Genital sensations associated with PGAD include throbbing, lubrication, pelvic congestion, sense of imminent orgasm without climax, and unprovoked orgasm (Waldinger and Schweitzer, 2009). The degree of distress is apparent

In a randomized controlled study in 24 women with orgasmic disorder, apomorphine 3 mg sublingual was superior to placebo in enhancing objective and subjective arousal and lubrication after application of a vibrator to the genitals. Nausea and vertigo were the most common side effects (Bechara et al, 2004). An open-label study demonstrated no benefit in 80% of women taking apomorphine 2 or 3 mg sublingual for HSDD or arousal disorders; in a follow-up randomized study, improvements in various spheres of sexual life were reported (Caruso et al, 2004). The unusual methodology of this study warrants caution in interpreting results.

A variety of other oral agents have been used in small randomized controlled studies of FSAD with some evidence of benefit for objective arousal responses. Examples include L-arginine with yohimbine (Meston and Worcel, 2002) and Korean red ginseng (Oh et al, 2010). Data on these therapies is scant and they should hence be viewed as experimental.

Topical Agents

One of the simplest approaches to GFASD is use of a sexual lubricant (Herbenick et al, 2011a). There are innumerable brands and formulations of sexual lubricants; they vary in terms of lubricity, additives, durability, and cost. Women who report dissatisfaction with one lubricant should be encouraged to investigate alternatives (Queen, 2013).

There are a variety of lubricants available that may be divided into three main categories.

1. Water-based (e.g., saliva and water-based commercial lubricants): safe for use with latex condoms and easy to wash off. May dry out and require repeat application.
2. Silicone-based: safe for use with latex condoms and easy to wash off. Less likely to dry out but more difficult to wash off. May have an unpleasant taste.
3. Oil-based (e.g., vegetable oils, butter, etc.): not safe for use with latex condoms. Less likely to dry out but more difficult to wash off.

It is important to note that most lubricants have spermatotoxic properties and may interfere with conception (Vargas et al, 2011). Couples that are attempting to conceive should avoid the use of most commercially available lubricants and saliva. Sperm-safe alternatives are available.

Transdermal Agents

Transdermal agents are designed to be absorbed through the skin and modulate the physiology of deep tissues. These differ in that respect from topical agents, which are designed to remain on the skin surface (e.g., sexual lubricants).

Transdermal prostaglandin E₁ (PGE₁) applied to the vulva and/or clitoris has been reported as a therapy for GFASD. One gram of ointment containing 0.2% PGE₁ applied to the external genitalia produced a more robust genital response when compared to placebo ointment (Bechara et al, 2003). A 2008 study demonstrated a significant improvement in survey scores and overall satisfaction with sexual arousal in women treated with PGE₁ versus placebo (Liao et al, 2008). Side effects of PGE₁ include localized irritation, soreness, and burning (Padma-Nathan et al, 2003; Liao et al, 2008).

A 16-week randomized, placebo-controlled study included 256 women with a variety of sexual concerns (including HSDD, FSAD, and orgasmic disorder) and sexual distress (per the FSDS) in response to on-demand vaginal treatment with a proprietary botanical agent. Women receiving the herbal compound reported higher mean FSFI desire and arousal scores compared to women receiving placebo. Scores for other domains did not reach statistical significance and overall FSFI score was not significantly different between treatment and placebo groups (mean increase of 2.1 vs. 0.9, respectively) (Ferguson et al, 2010).

In a single study the use of the adrenergic antagonist phentolamine as an oral pill or vaginal solution in 40 postmenopausal women with FSAD was investigated. In women receiving hormone therapy, a 40-mg dose of phentolamine led to significantly greater improvement in subjective arousal and vaginal blood flow as assessed by plethysmography. The most common side effects were rhinitis and headache (Rubio-Aurioles et al, 2002).

Hormones

Hormonal modulation may play an important role in the management of GFASD related to hypoestrogenic and/or hypoandrogenic states (Bachmann and Oza, 2006; Utian et al, 2008). Estrogens, SERMs, and the synthetic hormone tibolone may prove efficacious in treating FSAD (Laan et al, 2001; Gast et al, 2009).

from the fact that more than 20% of women presenting with PGAD in one series requested clitorrectomy for management (Waldinger and Schweitzer, 2009). On the other hand, unprovoked sexual arousal may engender positive feelings in some women (Leiblum and Chivers, 2007).

Reliable data on the prevalence of PGAD are scant (Leiblum and Nathan, 2001; Waldinger et al, 2009). A survey of 96 women presenting to a sexual health clinic indicated that just one patient met the full five-point criteria for PGAD. Importantly, about one third reported at least one symptom of PGAD (Garvey et al, 2009). Whether this represents a continuum of PGAD severity or a difference in subjective perception of bother is unclear.

Etiology

PGAD has been associated with a dysfunction of sexual beliefs (Carvalho et al, 2013) and restless legs syndrome (Waldinger and Schweitzer, 2009). PGAD has also been associated with anxiety and obsessive-compulsive symptoms (Leiblum and Chivers, 2007), dietary soy intake (Amsterdam et al, 2005), sleep disturbances (Wylie et al, 2006), periclitoral masses (Bedell et al, 2014), spinal tumors, withdrawal of SSRI medications (Goldmeier et al, 2006; Leiblum and Goldmeier, 2008), and pelvic arteriovenous malformations (Goldstein et al, 1995).

The largest series of women with confirmed PGAD included 18 Dutch women. It was reported that two thirds of the women presenting with PGAD were menopausal. Also noted was a high (55%) prevalence of pelvic varices; it is unclear whether or not menopause and the prevalence of pelvic varices are related, as varices are common in older women (Waldinger et al, 2009). Additional evaluations (brain MRI, pelvic MRI, electroencephalogram, transvaginal ultrasound, and serum hormone levels) were not conclusively demonstrative of any abnormalities (Waldinger et al, 2009). However, clinical examination of these women demonstrated that two thirds of them had restless legs syndrome and/or overactive bladder (Waldinger and Schweitzer, 2009). Many women also reported exacerbation of PGAD symptoms with stress. The authors hypothesized that PGAD may be a manifestation of nonsexual "hyperexcitability" of the genitals.

Evaluation

A careful physical examination may show genital anomalies that predispose to recurrent and unwanted sexual stimulus. Hormonal evaluation is warranted. If there are other neurologic signs, spinal MRI may be of some use.

Treatment

Waldinger and colleagues (2009) reported durable efficacy of the benzodiazepine drug clonazepam (0.5 to 1.5 mg/day) in reducing PGAD symptoms in 56% of treated subjects; benefit was also reported in some women from treatment with tramadol 50 mg or oxazepam 10 mg (Waldinger and Schweitzer, 2009).

Cognitive/behavioral treatments have been proposed, including training to direct attention away from genital sensations and the reduction of overall anxiety (Leiblum and Chivers, 2007). Women with this poorly understood disorder have very positive responses to empathy and support from their providers (Waldinger and Schweitzer, 2009).

FEMALE ORGASMIC DISORDER

Etiology

For diagnosis of female orgasmic disorder (FOD), the term "sufficient sexual stimulation" must be kept in mind. A substantial number of healthy women do not climax from vaginal penetration; others may experience climax from penetration but only after prolonged stimulation. These are normal variants of female sexual response.

There is a widespread cultural belief (derived in large part by the theories of Sigmund Freud) that vaginal penetration should lead to orgasm and that an absence of orgasm from penetration is indicative of psychopathology (Freud, 1905). Some authors have reported superior sexual and life functioning in women who climax from vaginal penetration (Nicholas et al, 2008; Brody and Costa, 2011). Although coitus-associated orgasms may be physically possible but inhibited in some women, there is no reliable data indicating that women who rely on stimulation of the glans clitoris for sexual climax are abnormal (Colson, 2010). Such women should be encouraged to explore nonpenetrative sexual stimuli that lead to climax without being informed that they are frigid or otherwise dysfunctional.

The quality of the relationship influences a woman's capacity to experience orgasm during sex. Poor communication (Kelly et al, 2004) and relationship conflict (Dennerstein et al, 1999) are associated with a lower likelihood of orgasm in women. Psychosocial issues and depression also exert a substantial negative influence on orgasmic capacity in women (Laumann et al, 1999). Antidepressant drugs are associated with FOD (Rosen et al, 1999a).

There are conflicting data on whether orgasm problems are more frequent based on sociodemographic variables. No definite trends have been identified based on age, ethnicity, or menopausal status (Graham, 2010). Similarly, there has been investigation of genetic or hereditary factors; preliminary results have suggested that there may be some genetic component related to difficulty with orgasm but further studies are needed (Witting et al, 2009). Surgical therapy or disruption of the genitals has been linked to FOD in women; this is most likely a result of psychological distress and/or disruption of the earlier phases of sexual response (Graham, 2010).

Evaluation

The general evaluation of sexual health should be performed. It should be determined whether or not the woman is receiving the adequate sexual stimulation that leads to orgasm for her (Basson et al, 2000). Assessment of patient/partner perceptions is essential.

Treatment

Directed masturbation is one of few therapies that has been shown efficacious for FOD (Andersen, 1981; Heiman and Meston, 1997). Frank and honest discussion between partners on preferred erotic activity is essential. This may require education of the woman and her partner on the normalcy of variations in sexual preferences and responses. Incorporation of clitoral or other erotic stimulation may be a satisfactory means to resolve FOD in some women.

Other behavioral interventions are detailed on the Expert Consult website. 

There are no approved pharmacotherapies for FOD. PDE5I enhance orgasmic response in women with decreased sexual desire related to the use of SSRI drugs (Nurnberg et al, 2008) and in postmenopausal women with orgasmic dysfunction (Cavalcanti et al, 2008). Use of these drugs in women is off label. Estrogens and androgens may be of benefit for women with FOD (Gast et al, 2009). These effects are likely driven by enhancement of earlier phases of sexual response and no study groups have investigated hormone manipulations with a primary end point of orgasm.

SEXUAL PAIN DISORDERS

Etiology

Genital and sexual pain disorders are often complex and multifactorial (Pauls and Berman, 2002). Regardless of initial etiology, pain with intercourse is likely to trigger a number of physical and psychological defense mechanisms that will further increase pain with sexual activity (Pauls and Berman, 2002). For instance, a woman with neuroproliferative vestibulodynia who experiences pain with

A 2008 report suggested that masturbation was more frequent in women who report frequent coital intercourse, a pattern that was reversed in men. A number of other sexual behaviors and a greater number of partners were also associated with more frequent masturbation ([Gerressu et al, 2008](#)). It may be inferred that masturbation is a supplement rather than a replacement for partnered sexual activity in women; it may also be a means to reach orgasm in women who do not routinely climax during partnered sex.

Sensate focus is a learning process of progressive body exploration; attention in sensate focus is directed away from genital

stimulation and the goal-oriented pursuit of orgasm and is directed toward full-body sensation and mutual pleasure. A graduated sequence of steps is performed throughout several weeks, leading eventually to penetrative intercourse. The general principle is to reduce anxiety and the goal-oriented pursuit of orgasm that may be self-defeating. This technique was introduced by Masters and Johnson and has been widely advocated by sex therapists, although long-term outcome data are sparse ([Masters and Johnson, 1966](#)).

BOX 32-2 Conditions Commonly Associated with Sexual Pain**SUPERFICIAL**

Neuroproliferative vestibulodynia
 Vulvar dermatoses
 Vulvovaginal atrophy
 Condyloma

DEEP

Endometriosis
 Interstitial cystitis
 Pelvic floor muscle dysfunction
 Uterine leiomyoma
 Pelvic inflammatory disease
 Pelvic fracture
 Pelvic radiation
 Vulvovaginal atrophy

Modified from Boardman LA, Stockdale CK. Sexual pain. Clin Obstet Gynecol 2009;52:682–90; and Vallier HA, Cureton BA, Schubeck D. Pelvic ring injury is associated with sexual dysfunction in women. J Orthop Trauma 2012;26:308–13.

intercourse will likely experience anxiety and impairment of genital arousal/lubrication with her next sexual encounter. Enhanced pelvic muscle tone may occur as a defense mechanism. This constellation of downstream effects will generally compound on one another. There is often a substantial delay between the onset of symptoms and the presentation for evaluation, and many presenting women have experienced genital pain as a result of numerous contributing factors (Pauls and Berman, 2002).

A list of conditions known to be associated with sexual pain disorders is presented in Box 32-2. Studies in adolescent and young adult women (<25 years of age) indicated that between 20% and 57% report pain with intercourse (Landry and Bergeron, 2009). Sexual pain is also prevalent in older women, most commonly from vulvovaginal atrophy (Farage and Maibach, 2006). The most common cause of vulvovaginal atrophy is estrogen deficiency related to menopause (surgical or natural) (North American Menopause Society, 2013). Pelvic radiation may also contribute to vaginal atrophy (Incrocci and Jensen, 2013).

Superficial dyspareunia may result from neuroproliferation of the vulvar vestibule. The vulvar vestibule is of endodermal origin and is hence embryologic and histologically distinct from the adjacent vaginal mucosa and vulvar squamous epithelium (O'Connell et al, 2008). This area may become hypersensitive, with tactile allodynia prohibitive of sexual contact (Zolnoun et al, 2006). Vulvar dermatoses are common and may be frequently missed as causes of superficial dyspareunia (Burrows et al, 2008). A retrospective review of patients seen in a tertiary referral center for vulvovaginal disorders reported that more than 60% of women had some form of vulvar dermatosis (Bowen et al, 2008). Deep dyspareunia has been associated with other gynecologic conditions such as uterine leiomyoma, ovarian cysts, and endometriosis (Vercellini et al, 2012).

The importance of mental, cognitive, and partner-related factors cannot be overlooked in any pain disorder. Anxiety and mood disorders are common in women with dyspareunia; attention to these factors is an essential part of treatment (Basson et al, 2010b). Women with high levels of relationship intimacy and partner support generally report less bother related to sexual pain disorders (Bois et al, 2013). Women from conservative, religious, and/or sexually repressive backgrounds are more likely to report sexual pain (Yasan and Gorgen, 2009). Pain that is prohibitive of sexual activity may also occur in victims of sexual abuse or trauma (Nusbaum et al, 2005; World Health Organization, 2013). Fear of pain, catastrophizing

thoughts (i.e., exaggerated negative thoughts about pain), and loss of self-efficacy (e.g., thoughts such as “I’ll never be able to have good sex” or “there is nothing I can do to make it hurt less”) have all been linked to worse pain with sexual activity. Loss of self-efficacy has been reported as the most influential mental variable in patients with genital pain during sex (Desrochers et al, 2009).

Evaluation

The onset of sexual pain is very relevant; a woman who experienced lifelong difficulty with sexual activity may have a congenital or psychological etiology for pain. A woman who previously enjoyed sexual activity but now finds it painful is likely to have a musculo-skeletal, pelvic, genital, dermatologic, or psychological etiology.

Evaluation of sexual pain relies heavily on physical examination. Careful inspection of the entirety of the external genitalia is essential, as subtle pathology may be easily missed. Inspection of the vulva and labia majora may show dermatologic conditions such as lichen planus (LP), lichen simplex chronicus, lichen sclerosus, vulvar intraepithelial neoplasia (VIN), genital condyloma, contact dermatitis, or other lesions (Fig. 32-11 on the Expert Consult website). A biopsy may be warranted but should only be ordered to rule in or rule out a specific diagnosis.

After inspection of the vulva and labia majora, the labia minora, clitoris, and vulvar vestibule should be examined. Some degree of erythema is normal along the crease of the labia minora. Bartholin gland cysts, inflammation of Skene glands, clitoral phimosis, vulvar erythema, and labial fissures may be detected (Goldstein and Burrows, 2008). The endodermally derived vulvar vestibule is a site for superficial dyspareunia resulting from neuroproliferation (Fig. 32-12 on the Expert Consult website) (O'Connell et al, 2008). The line of demarcation between the endodermal vestibule, the ectodermal vulva, and the mesodermal vagina is subtle; precise examination is key to appropriate diagnosis. Regression/resorption of the labia minora is an important and often overlooked anomaly that is most commonly observed in women who are hormonally deficient (Goldstein and Burrows, 2008).

Assessment for vulvar sensation and tactile allodynia is recommended. This may be accomplished by application of a cotton swab, heat/cold, or a biothesiometer. Women with neuroproliferative vestibulodynia will have marked pain with even light contact against the vestibular tissue (Goldstein and Burrows, 2008).

Transvaginal palpation of the levator ani (LA) is essential. Transanal palpation may be an option in women unable to tolerate vaginal penetration. The patient should be asked to characterize palpation as pressure (normal) or pain (abnormal). Localization of pain permits more focal physical therapy and/or trigger-point injections. Palpation of the adnexa, uterus, and the pudendal nerves in the vicinity of the ischial tuberosity completes the examination (Goldstein and Burrows, 2008).

Treatment

The clitoris may not be involved in pain syndromes of the vestibule and vagina. Hence women with a sexual pain disorder may be able to experience sexual pleasure and bonding with a partner by means of clitoral stimulation. This may be a useful means to foster or maintain sexual intimacy while issues of vaginal and/or pelvic pain with intercourse are being addressed. A multimodal approach to the management of sexual pain is advisable. Psychobehavioral intervention to reduce anxiety surrounding sexual activity is crucial (Rosenbaum, 2011). Cognitive behavioral therapy, psychodynamic, and other therapeutic approaches have been used (Bergeron et al, 2001).

Treatment of Abdominopelvic Processes

Gynecologic conditions (uterine leiomyoma, cystic ovarian disease, endometriosis, labial fusion, vaginal septum, etc.) and other

Figure 32-11. A variety of vulvar conditions. A, Fibroadenoma of the hymen that caused dyspareunia. B, Persistent hymenal tissue in a young woman with dyspareunia. C, Stenosis of the introitus in a sexually inactive menopausal woman with pain wearing tight clothing and during sitting. D, Painful tearing of the posterior fourchette from sexual intercourse.

Figure 32-12. Neuroproliferative vestibulodynia. In some women with vestibulodynia and extreme allodynia, the following abnormalities have been found in the vestibular mucosa: (1) an increased density of C-afferent nociceptors, (2) a marked increase in mast cells, and (3) an increased expression of heparinase. It has been postulated that activated mast cells release nerve growth factor and heparinase, which leads to the proliferation of nociceptors. This form of vestibulodynia has been called neuroproliferative vestibulodynia and may be congenital or acquired. In some of these women, polymorphisms in genes have been found that code for various interleukins, a group of cytokines expressed by the immune system, and involved in wound healing. When neuroproliferative vestibulodynia is identified, complete vestibulectomy and vaginal advancement flap reconstruction may be considered.

pelvic disorders (irritable bowel, Crohn disease, etc.) may predispose women to dyspareunia. Appropriate medical or surgical treatment may be of benefit in addressing sexual dysfunction although adjunctive therapies may be required (Basson et al, 2010b).

Empiric Medical Therapy

Empiric therapies advanced for sex-related pain include fluconazole, cromolyn sodium, botulinum toxin injection, capsaicin, local anesthetics, desipramine, tricyclic, and novel antidepressants, anticonvulsants, montelukast, enoxaparin, monoclonal antibodies to tumor necrosis factor- α , sacral nerve stimulation, and combination therapies. The level of evidence supporting these interventions as empiric therapy is generally sparse (Kamdar et al, 2007; Koninckx et al, 2008; Bertolasi et al, 2009; Ramsay et al, 2009; Basson et al, 2010b).

Vulvar Dermatoses

Vulvar dermatoses are best managed with reassurance and routine hygiene. Antihistamines may be beneficial to break the cycle of warranted itching that exacerbates the condition of lichen simplex and contributes to other entities. Steroids should not be used empirically for the management of any sexual pain disorder without a diagnosis. Steroid therapy may be indicated in some specific cases; before treatment with steroids is initiated it is prudent to consider biopsy, particularly because there is a small but finite risk of malignant transformation in lichen sclerosus and LP (Salim and Wojnarowska, 2005).

Vulvovaginal Atrophy

Vaginal moisturizers are agents designed to restore baseline lubriciousness of the vagina. Such agents may be of use in addressing uncomfortable vaginal dryness and have been shown to enhance sexual pleasure for many women. It is important to note that such agents are not designed for use as sexual lubricants; they tend to dry out from friction during intercourse. There are numerous commercially available lubricants intended for use during sexual contact (see *Female Sexual Arousal Disorder*) (Herbenick et al, 2011a).

Systemic or local administration of estrogens has been linked to improvements in vaginal atrophy related to hypoestrogenism (North American Menopause Society, 2007). Local estrogen therapies need not be combined with progestins for endometrial protection when used at low doses (North American Menopause Society, 2013). A variety of estrogen preparations are available for local use; these may be administered as vaginal creams, suppositories, rings, pessaries, or tablets. Systemic absorption of vaginal estrogen preparations is generally very low (Weisberg et al, 2005; Simon et al, 2010; North American Menopause Society, 2013) and hence local therapy may be preferable for patients and providers who are concerned primarily with genital effects. Systemic estrogens may be of use in some women (Bachmann, 1995) but their use must be carefully considered in light of some controversy about long-term health risks (Utian et al, 2008; Jick et al, 2009).

Local and systemic androgens have also been investigated for the management of vaginal symptoms in women. Pilot studies have suggested improvements in symptoms of dyspareunia and vaginal pH after administration of local androgens with no changes in systemic T or E levels (Witherby et al, 2011). A meta-analysis of T therapy has confirmed a generalized benefit with respect to sexual function (arousal, lubrication, and pain) in women who received T supplementation, although safety data are limited (Somboonporn et al, 2005).

Intravaginal DHEA has also been used for treatment of dyspareunia related to vulvovaginal atrophy and has been shown to be superior to placebo for improvement in vaginal histology, pH, and pain with intercourse (Labrie et al, 2011). Further research on the

safety and efficacy profile of T and DHEA for vulvovaginal atrophy is warranted (Nappi and Davis, 2012).

Ospemifene is the first nonestrogen treatment approved by the FDA for the management of dyspareunia in postmenopausal women. Ospemifene is a SERM that includes estrogenic activity in bone and in the vaginal epithelium (Rutanen et al, 2003). Randomized controlled trials of oral ospemifene, 30 to 60 mg/day, have demonstrated superiority to placebo for improving vaginal histology, vaginal pH, and dyspareunia (Bachmann et al, 2010; Portman et al, 2013). The most common side effects of ospemifene are hot flashes, candidiasis, and urinary tract infection (Bachmann et al, 2010). In 1-year extension studies of ospemifene, continued benefits were noted with respect to dyspareunia. There was a low rate (0% to 1%) of endometrial proliferation; no carcinomas of the breast or endometrium were identified (Goldstein et al, 2013; Simon et al, 2013).

Musculoskeletal Dysfunction/Scarring

Pelvic floor physiotherapy is a treatment for pelvic/sexual pain related to musculoskeletal disorders. Directed massage, exercise, and pelvic floor biofeedback may durably ameliorate some forms of sexual pain (Rosenbaum, 2005; Bergeron et al, 2008). Progressive dilator therapy may be conducted in the office or at home for management of pain associated with penetration. The patient receives a set of progressively larger polymer dilators that can be inserted into the vagina. The size of the dilators inserted is increased gradually with the eventual goal of comfort with vaginal penetration. Compliance tends to be low without support and involvement from the provider (Rosenbaum, 2011).

Vaginal suppositories containing the benzodiazepine drug diazepam (10 mg) have been advocated by some experts for pelvic pain syndromes including dyspareunia. The FDA has not approved these medications for this indication, but several case reports have suggested efficacy as part of a multimodal treatment regimen (Rogalski et al, 2010). Muscle relaxants have also been used with the intent of decreasing somatic muscle contraction. These may be administered systemically or locally. Botulinum toxin may be effective as an injection for high-tone pelvic floor muscle dysfunction with vaginal spasm (Bertolasi et al, 2009; Goldstein et al, 2011; Nesbitt-Hawes et al, 2013).

Provoked/Neuroproliferative Vestibulodynia

Vulvar vestibulectomy is efficacious in the management of pain in the superficial external vulva related to neuroproliferation (Goldstein et al, 2006). A randomized study indicated superior results (based on intention to treat) of vestibulectomy compared to cognitive-behavioral therapy and biofeedback for dyspareunia (Bergeron et al, 2001). Benefits of treatment were maintained up to a follow-up of 2½ years post-treatment (Bergeron et al, 2008). Experienced and/or well-trained providers may offer vulvar vestibulectomy to patients who are carefully selected. **Patient selection is critical; this procedure should only be offered in the setting of neuroproliferative vestibulodynia affecting the vulvar vestibule** (Goldstein et al, 2006). Complete excision of all tissue between the Hart's line (junction between keratinized skin and mucosa) and the hymenal ring, with reapproximation of the vaginal mucosa to the vulvar skin, permits a satisfactory cosmetic result with removal of all affected tissue (Fig. 32-13 on the Expert Consult website) (Goldstein, 2006).

CONCLUSIONS

Female sexual function and dysfunction are important aspects of urologic practice. Urologists should be aware of the urologic ramifications of sexual issues and vice versa. Appropriate treatment (or referral) of women with sexual concerns will improve patient satisfaction and treatment compliance.

COMPLETE VESTIBULECTOMY REMOVING ALL VESTIBULAR TISSUE,
EVEN 1 TO 2 MM FROM THE URETHRAL MEATUS

Figure 32-13. A complete vestibulectomy may be considered for neuroproliferative vestibulodynia. The tissue for excision is marked with a blue pen intraoperatively and involves (1) the right and left anterior vestibule bounded by the urethral meatus and Hart's line of the labia minora and (2) the posterior vestibule bounded by Hart's line, the tissue just inside the hymen, and the perineum. After the tissue has been excised, reconstruction of the posterior fourchette defect is fashioned with a vaginal advancement flap. It is critical to remove the entire vestibule as the neuroproliferative process is a field disease.

KEY POINTS: FEMALE SEXUAL CONCERNS

- The etiology of sexual concerns in women is often multifactorial.
- There is substantial overlap between sexual concerns in women.
- There are few approved pharmacotherapies for female sexual concerns; there are a number of treatments, but many of these are off label.
- A multidisciplinary approach to sexual concerns with sensitivity to the woman's unique situation is most likely to be effective.
- Psychosocial support is critical in the management of any sexual concern.

Surgical, Radiographic, and Endoscopic Anatomy of the Retroperitoneum

Drew A. Palmer, MD, and Alireza Moinzadeh, MD

Body Surface Landmarks

Posterior Abdominal Wall

Lumbodorsal Fascia

Retroperitoneal Fasciae and Spaces

Gastrointestinal Viscera

Vasculature

Lymphatic System

Nervous Structures

To the astute urologist, anatomic knowledge of the retroperitoneum is critical for success. This chapter provides a thorough description of retroperitoneal anatomy, including the genitourinary organs, musculature, bony structures, fasciae, vessels, lymphatics, neural structures, and gastrointestinal viscera. See [Table 33-1](#) on the Expert Consult website for a review of the anatomic and surgical history of the retroperitoneum.

The retroperitoneum can be described as the entirety of the structures contained anteriorly by the posterior reflection of the peritoneum, posteriorly by the abdominal wall, cranially by the diaphragm, and caudally by the extraperitoneal pelvic structures ([Fig. 33-1](#)). The last term must be distinguished from *extraperitoneal space*, which includes the retroperitoneum and the space that circumferentially surrounds the abdominal cavity ([Miralis and Skandalakis, 2009, 2010a, 2010b, 2010c, 2010d](#)).

The contents of the retroperitoneum include the **kidneys, ureters, adrenals, pancreas, portions of the duodenum, ascending colon, descending colon, arterial structures including the aorta and its branches, venous structures including the inferior vena cava (IVC) and its tributaries, lymphatics, lymph nodes, sympathetic trunk, and lumbosacral plexus** ([Fig. 33-2](#) on the Expert Consult website and [Box 33-1](#); also see [Fig. 33-1](#)).

BODY SURFACE LANDMARKS

The ability to identify abdominal organs using physical examination has great utility for clinical diagnosis and operative planning. The location of the kidneys can be estimated based on their relationship to the bony structures of the posterior abdominal wall ([Fig. 33-3](#)). The upper pole of the left kidney is typically located at the level of the 11th rib. The right kidney lies lower than the left, with its upper pole at the level of the 12th rib. The lower poles of the kidneys are between the L3 and L4 vertebrae, and the **renal hila** are approximately at the level of L1.

POSTERIOR ABDOMINAL WALL

Flank Muscles ([Figs. 33-4 to 33-7](#) and [Table 33-2](#))

The most superficial of the flank muscles is the **external oblique**, which lies beneath the subcutaneous fascia. It originates from ribs

5 through 12, and its muscle fibers travel inferomedially inserting at the iliac crest and ending in the midline at the linea alba. **The inferior border of the aponeurosis of the external oblique forms the inguinal ligament.** Deep to the external oblique lies the **internal oblique**, which originates from the lumbodorsal fascia and the

BOX 33-1 Organs and Structures of the Retroperitoneum

ORGANS

Kidneys (PR)
Ureters (PR)
Adrenal glands (PR)
Portions of the duodenum (SR)
Ascending colon (SR)
Descending colon (SR)
Pancreas (SR)

VESSELS

Abdominal aorta (and its branches)
Inferior vena cava (and its tributaries)
Ascending lumbar veins
Portal vein

TABLE 33-2 Musculature of the Posterior and Lateral Abdominal Wall

MUSCLE	ORIGIN	INSERTION	FUNCTION
Erector spinae	Sacrum and vertebrae	Lower ribs and vertebrae	Extension of spine
External oblique	Ribs 5-12	Lateral lip of iliac crest, aponeurosis ending in linea alba	Compress abdominal contents, flexion of trunk
Internal oblique	Lumbodorsal fascia, iliac crest, inguinal ligament	Lower four ribs, aponeurosis ending in linea alba, pubic crest	Compress abdominal contents, flexion of trunk
Transversus abdominis	Lumbodorsal fascia, medial lip of iliac crest, ribs 7-12	Aponeurosis ending in linea alba, pubic crest	Compress abdominal contents
Psoas major	T12-L5 vertebrae	Lesser trochanter of femur	Flexion of hip
Psoas minor	T12 and L1 vertebrae	Pelvic brim, iliopubic eminence	Weak flexion of lumbar vertebral column
Iliacus	Iliac fossa, sacrum	Lesser trochanter of femur	Flexion of the hip
Quadratus lumborum	5th lumbar vertebra, iliac crest	L1-L4 vertebrae, 12th rib	Depress and stabilize 12th rib, lateral bending of trunk

Modified from Drake RL, Vogl AW, Mitchell AWM. Gray's anatomy for students. Philadelphia: Churchill Livingstone; 2005.

iliac crest. It travels superomedially inserting at the lower ribs and linea alba. Each of these muscle layers is invested in a layer of fascia. The **transversus abdominis** muscle, named because of the *transverse* direction of its muscle fibers, lies deep to the internal oblique. Deep to the transversus abdominis muscle lies the **transversalis fascia**, which crosses the midline anteriorly and fuses with the lumbodorsal fascia posteriorly. These flank muscles function to flex, extend, and rotate the trunk and provide compression of the abdominal contents.

Psoas, Iliacus, Quadratus Lumborum, and Erector Spinae (Fig. 33-8; also see Figs. 33-4 to 33-7 and Table 33-2)

The **psoas major** muscle arises from the 12th thoracic vertebra to the 5th lumbar vertebra to attach to the lesser trochanter of the femur after traveling along the pelvic brim posterior to the inguinal ligament. The psoas minor muscle, which may be absent in some individuals, originates at T12 and L1 and inserts at the pelvic brim and iliopubic eminence. The psoas major functions in flexion of the thigh at the hip joint and is innervated by the anterior rami of L1, L2, and L3. The **iliacus** muscle originates at the caudal aspect of the iliac fossa and the lateral sacrum to insert at the lesser trochanter of the femur. It functions in flexion of the thigh at the hip joint along with the psoas major. The **quadratus lumborum** lies posterior and medial to the psoas muscle and assists with lateral bending of the trunk and stabilization of the 12th rib. Its origin is at L5 and the iliac fossa, and it attaches to the inferior border of the 12th rib and the transverse processes of L1-L4. The **erector spinae (sacrospinalis)** is a large group of back muscles that function to extend the spine.

Spine

The spine consists of 7 cervical vertebrae, 12 thoracic vertebrae, 5 lumbar vertebrae, the sacrum, and the coccyx. Each vertebra has a large weight-bearing area called the **vertebral body** and a posterior and lateral arch that forms the vertebral foramen (Fig. 33-9 on the Expert Consult website). The **spinous process** projects posteroinferiorly, and the **transverse processes** project posterolaterally. The lumbar vertebrae are the most clinically significant in regard to the retroperitoneum. They are larger than the other vertebrae with generally long, thin transverse processes.

The vertebral column levels have different relationships with the spinal cord segmental levels at different locations within the

Figure 33-8. Muscles of the posterior abdominal wall. (From Drake RL, Vogl AW, Mitchell AWM. Gray's anatomy for students. 2nd ed. Philadelphia: Churchill Livingstone; 2010.)

spinal column. For example, the sacral spinal cord segmental levels typically begin between vertebral column level T12 and L1 in adults. When discussing spinal cord injury, one must be careful to specify vertebral column level versus spinal segmental level.

Figure 33-9. Typical vertebrae. (From Drake RL, Vogl AW, Mitchell AWM. *Gray's anatomy for students*. 2nd ed. Philadelphia: Churchill Livingstone; 2010.)

Figure 33-11. Intercostal neurovascular bundle. (From MacLennan GT. *Hinman's atlas of uro-surgical anatomy*. 2nd ed. Philadelphia: Saunders; 2012.)

10th, 11th, and 12th Ribs

The lower ribs function to protect the retroperitoneal structures from traumatic injury. Fracture of these lower ribs should lead to a high clinical suspicion for injury to the retroperitoneal structures (Fig. 33-10 on the Expert Consult website). The lower ribs differ from the upper ribs given their shorter length with less pronounced angulation. The 10th rib articulates with the body of the vertebra at its head and the transverse process at its neck. The 11th rib lacks a neck and does not articulate with the transverse process. The angle of the 11th rib is less pronounced than that of the upper ribs. The 12th rib has no angle and is shorter than the other ribs. Its inferior border is attached to the transverse processes of L1 and L2 by the costovertebral (lumbocostal) ligament, which can be incised to allow for increased mobility for greater exposure of the upper retroperitoneum during posterior approaches. Similar increased mobility may be achieved by dividing a thick fibrous band known as the intercostal ligament found between other ribs.

The 11th and 12th ribs must be distinguished from the other ribs because they have no anterior connection with the sternum and are often referred to as *floating ribs*. These ribs are of clinical significance during palpation for the marking of a surgical incision.

The intercostal vessels and nerves travel between the internal intercostal and innermost intercostal muscles within the costal groove on the caudal margin of the superior rib (Fig. 33-11). The vein is the most superior structure with the artery running inferior to it. The intercostal nerve is the most inferior of the three structures and is often not protected by the costal groove.

LUMBODORSAL FASCIA

The lumbodorsal (thoracolumbar) fascia is composed of three distinct layers that invest the posterior abdominal wall musculature (Fig. 33-12). These three layers merge into one as they travel laterally. A common access point to the retroperitoneum is near the tip of the 12th rib, where all layers have merged into one. This single layer of lumbodorsal fascia merges with the aponeurosis of the transversus abdominis muscle anterolaterally. The **posterior lamella** originates medially from the spinous process of the lumbar vertebrae and covers the erector spinae muscles. The **middle lamella**

Figure 33-12. Lumbodorsal fascia and the deep back muscle. (From Drake RL, Vogl AW, Mitchell AWM. *Gray's anatomy for students*. 2nd ed. Philadelphia: Churchill Livingstone; 2010.)

separates these erector spinae muscles from quadratus lumborum. The anterior lamella covers the ventral surface of quadratus lumborum. Extending medially, the **anterior lamella** attaches to the vertebral transverse process and is continuous with the fascia that invests the psoas muscle.

The retroperitoneum can be entered without incising muscle using a dorsal lumbotomy incision (Fig. 33-13). This approach uses a vertical incision through the lumbodorsal fascia lateral to the erector spinae and quadratus lumborum muscles (Fig. 33-14 on the Expert Consult website).

RETROPERITONEAL FASCIAE AND SPACES

Derived from the mesoderm, the primitive mesenchyme differentiates to form a subcutaneous layer, body layer, and retroperitoneal

Figure 33-10. Structures related to the posterior surface of the kidney. (From Drake RL, Vogl AW, Mitchell AWM. *Gray's anatomy for students*. 2nd ed. Philadelphia: Churchill Livingstone; 2010.)

Figure 33-14. Posterior approach to the kidney through the lumbodorsal fascia. (From MacLennan GT. *Hinman's atlas of urosurgical anatomy*. 2nd ed. Philadelphia: Saunders; 2012.)

Figure 33-13. Transverse section through the kidney and posterior abdominal wall showing the lumbodorsal fascia incised. Through such a lumbodorsal incision, the kidney can be reached without incising muscle. (After Kelly and Burnam, from McVay C. Anson & McVay surgical anatomy. 6th ed. Philadelphia: Saunders; 1984.)

layer. The retroperitoneal layer forms three strata in late fetal development: the outer stratum, intermediate stratum, and inner stratum (Fig. 33-15 on the Expert Consult website). Historically, the retroperitoneum has been divided embryologically based on these three strata (Tobin, 1944). The **outer stratum** covers the epimysium of the abdominal wall muscles and becomes the transversalis fascia. The **intermediate stratum** is associated with the urinary organs, and the **inner stratum** is associated with the gastrointestinal organs (MacLennan, 2012). The aim is not to have the reader memorize what each embryologic stratum becomes during development. Rather, these embryologic strata serve to categorize the retroperitoneal fasciae, which compartmentalize various spaces within the retroperitoneum.

Transversalis Fascia and Posterior Pararenal Space

The outer stratum forms the **transversalis fascia**, which lies deep to the transversus abdominis muscle and superficial to the preperitoneal fat and peritoneum. Posterior to the kidney, the transversalis fascia remains anterior to the fascia surrounding the quadratus lumborum and psoas muscle (Fig. 33-16). It may fuse medially with the posterior lamina of Gerota fascia, which is of clinical significance during retroperitoneal dissection because this fascia must be incised to allow access to the renal hilum. This fusion creates the medial boundary of the posterior pararenal space. The anterior boundary is formed by the posterior lamina of Gerota fascia, and the posterior and lateral boundaries are formed by the transversalis fascia (Tobin, 1944).

Gerota Fascia (Renal Fascia) and Perirenal Space (Figs. 33-17 and 33-18; also see Fig. 33-16)

The anterior lamina (fascia of Toldt or prerenal fascia) and the posterior lamina (fascia of Zuckerkandl or retrorenal fascia) of the renal fascia are derived from the intermediate stratum, which embeds the genitourinary organs. They help to form the boundaries of the retroperitoneal spaces: the posterior pararenal space,

perirenal space, and anterior pararenal space. The two laminae together form the **renal fascia**, eponymously named *Gerota fascia*, after the Romanian anatomist Dimitrie D. Gerota (1867-1939). The **perirenal space** contains the adrenal, kidney, ureter, perirenal fat, renal vascular pedicle, and gonadal vessels. The perirenal fat is finer and lighter yellow in color compared with the coarser yellow-orange pararenal fat. The anatomy of the adrenal, kidney, and ureter is discussed in detail in their respective chapters.

The posterior lamina of Gerota fascia is thicker and more frequently visualized radiographically than the anterior lamina. These two layers merge laterally to form the **lateroconal fascia**, which separates the anterior and posterior pararenal spaces and continues anterolaterally deep to the transversalis fascia. There is some controversy regarding the medial and inferior extents of the perirenal space. Historically, it was assumed that there was no communication between the right and left perirenal spaces. However, based on in vivo cases and cadaveric injection studies, **there may be some communication across the midline below the level of the renal hilum** (Lim et al, 1998).

In addition, there has been no consensus on the patency and caudal extent of the perirenal space. Previously, it was suggested that the perirenal space is closed inferiorly by the fusion of Gerota fascia. However, in vivo cases and cadaveric injection studies demonstrated that the **perirenal space has a conelike shape that is open at its inferior extent in the extraperitoneal pelvis** (Lim et al, 1998). These boundaries are of tremendous clinical significance in the pathology of urologic disease because they function to contain perinephric fluid collections, which include urine (traumatic or iatrogenic urinary extravasation, obstructive uropathy with calyceal rupture), blood (traumatic or iatrogenic perinephric hematoma, ruptured aneurysm), or purulence (perinephric abscess or infected urinoma).

Anterior Pararenal Space and Inner Stratum

The **anterior pararenal space** is formed by the anterior lamina of the renal fascia posteriorly and the posterior layer of parietal peritoneum anteriorly (Fig. 33-19 on the Expert Consult website).

Figure 33-15. Retroperitoneal fascial development at 5 weeks. (Modified from Skandalakis JE, Colborn GL. *Skandalakis' surgical anatomy: the embryological and anatomic basis of modern surgery*. Athens, Greece: Paschalides Medical Publications; 2004.)

Figure 33-18. Posterior view of Gerota fascia on the right side, rotated medially with the contained kidney, ureter, and gonadal vessels, exposing the muscular posterior body wall covered by the transversalis fascia. (From Tobin CE. The renal fascia and its relation to the transversalis fascia. *Anat Rec* 1944;89:295–311.)

Figure 33-21. Colon, duodenum, and pancreas within the retroperitoneum. (From Drake RL, Vogl AW, Mitchell AWM. *Gray's anatomy for students*. 2nd ed. Philadelphia: Churchill Livingstone; 2010.)

Clinically, this space is significant because it can be developed to gain access to the kidney anteriorly when followed medially from the **white line of Toldt**. This classic landmark is created during embryogenesis when the inner stratum forms a multilayer fusion fascia with the primary dorsal peritoneum during the rotation and posterior attachment of the gastrointestinal viscera (Fig. 33-20 on the Expert Consult website). **During this event, the white line of Toldt is formed at the lateral border of the fusion of the colonic mesentery with the posterior peritoneum.**

The anterior pararenal space contains the secondarily retroperitoneal organs: the ascending and descending colon, pancreas, and second and third portions of the duodenum. These organs are intraperitoneal at one point during embryogenesis; however, they become retroperitoneal secondarily as they attach to the posterior abdominal wall when the inner stratum fuses with the primary dorsal peritoneum.

GASTROINTESTINAL VISCERA

The nonurologic viscera within the retroperitoneum includes the pancreas and parts of the duodenum and the colon (Figs. 33-21 and 33-22). The **pancreas** consists of four parts and has endocrine and exocrine functions. The head lies anterior to the IVC and is surrounded by the second portion of the duodenum. This portion is of concern for potential injury during right kidney procedures. The neck connects the head to the body, which crosses the abdomen anterior to the aorta and the origin of the superior mesenteric artery (SMA).

The tail of the pancreas is closely associated with the spleen and must be accounted for during left retroperitoneal surgery because of its proximity to the upper pole of the left kidney and left adrenal. In addition, the stomach is anterior to the upper pole of the left kidney and must be accounted for during transperitoneal left renal surgery (Fig. 33-23 on the Expert Consult website).

The **duodenum** is 20 cm to 25 cm in length and can be divided into four distinct parts. The first (superior) portion is intraperitoneal and extends from the pylorus to the neck of the gallbladder. The second (descending) and third (horizontal or inferior) portions of the duodenum are contained within the retroperitoneum. **The second, descending portion of the duodenum is of critical importance to the urologist because of its proximity to the right renal hilum.** The duodenum may be mobilized medially using a **Kocher maneuver** to expose these right-sided retroperitoneal structures. The common bile duct and the main pancreatic duct combine to enter the second portion of the duodenum at the ampulla of Vater (hepatopancreatic ampulla). The third portion of the duodenum crosses the body from right to left and lies posterior to the SMA and anterior to the aorta. The fourth and final portion ascends and becomes intraperitoneal as it transitions into the jejunum.

As with the duodenum, portions of the colon are secondarily retroperitoneal because they developed intraperitoneally but fused with the posterior abdominal wall during embryogenesis. The **ascending colon** and hepatic flexure overlie the right-sided retroperitoneal structures, and the splenic flexure and **descending colon** cover the left-sided retroperitoneal structures. To gain access

Figure 33-27. Inferior vena cava and its tributaries and abdominal aorta and its branches.

to the kidneys transperitoneally, the ipsilateral colon must be reflected medially in most instances. This can be performed by mobilizing the colon at the white line of Toldt, which visually represents the transition from the colonic visceral peritoneum to the posterior parietal peritoneum. Care must be taken to divide the hepatocolic and splenocolic ligaments sharply when necessary to avoid iatrogenic injury to the liver and spleen, which is often due to excessive retraction during attempts to obtain adequate exposure.

VASCULATURE

Arterial System

Arterial structures have three layers: the tunica intima (intima), tunica media (media), and tunica externa (tunica adventitia or adventitia) as shown in Figure 33-24 on the Expert Consult website. The **intima** consists of a layer of endothelial cells surrounded by subendothelial connective tissue. The **media** layer contains vascular smooth muscle cells and elastic connective tissue that control the caliber of the vessel. This layer is surrounded by the internal and external elastic laminae. The **adventitia** is the connective tissue sheath surrounding the vessel. It contains the nerves that control vasomotor tone and the vasa vasorum (Latin, “vessels of the vessels”), which are smaller vessels that supply the walls of larger vessels.

The major arterial structures of the retroperitoneum include the abdominal aorta (Figs. 33-25 and 33-26 on the Expert Consult website) and its branches (Fig. 33-27 and Table 33-3). Entering the abdomen through the aortic hiatus of the diaphragm at the level of

T12, the **abdominal aorta** courses centrally and to the left of the IVC. The first branches are the paired **inferior phrenic arteries**, which supply the inferior surface of the diaphragm (Fig. 33-28 on the Expert Consult website). The **superior adrenal artery** branches from the inferior phrenic artery and supplies the ipsilateral adrenal gland. The superior arterial blood supply to the adrenal is constant; however, the middle and inferior arteries to the adrenal are variable. These arteries vary in number and location with the most common variant being the middle adrenal artery arising from the aorta and the inferior adrenal arising from the renal artery.

The next branch of the abdominal aorta is the **celiac artery** (celiac trunk or truncus coeliacus) which is a short, unpaired artery that arises anteriorly at the midline at the level of T12. It gives origin to the left gastric, splenic, and common hepatic arteries, which supply the abdominal esophagus, stomach, duodenum, spleen, liver, and pancreas. Of surgical anatomic significance, the splenic vessels course on the cephalad aspect of the body and tail of the pancreas. When the inferior pancreatic edge is mobilized off the anterior renal fascia during adrenal or renal transperitoneal surgery, knowledge of the anatomic relationship between the splenic vessels and the pancreas is paramount to prevent vascular injury. The next branches are the paired middle adrenal arteries, which supply the ipsilateral adrenal gland as noted earlier.

The SMA branches next off the aorta, arising anteriorly in the midline at approximately the level of the middle adrenal arteries at L1-L2. It supplies the pancreas (inferior pancreaticoduodenal artery), small intestine, and most of the large intestine (ileocolic, right colic, and middle colic arteries). The **middle colic artery** anastomoses with the left colic artery off the inferior mesenteric

TABLE 33-3 Branches of the Abdominal Aorta

ARTERY	BRANCH	ORIGIN	SUPPLIES
Celiac trunk	Anterior	Immediately inferior to aortic hiatus of diaphragm	Abdominal foregut
Superior mesenteric artery	Anterior	Immediately inferior to celiac trunk	Abdominal midgut
Inferior mesenteric artery	Anterior	Inferior to renal arteries	Abdominal hindgut
Middle adrenal arteries	Lateral	Immediately superior to renal arteries	Adrenal glands
Renal arteries	Lateral	Immediately inferior to superior mesenteric artery	Kidneys
Testicular or ovarian arteries	Paired anterior	Inferior to renal arteries	Testes in male and ovaries in female
Inferior phrenic arteries	Paired lateral	Immediately inferior to aortic hiatus	Diaphragm
Lumbar arteries	Posterior	Usually four pairs	Posterior abdominal wall and spinal cord
Median sacral arteries	Posterior	Just superior to aortic bifurcation, pass inferiorly across lumbar vertebrae, sacrum, and coccyx	
Common iliac arteries	Terminal	Bifurcation usually occurs at level of L4 vertebra	

Modified from Drake RL, Vogl AW, Mitchell AWM. Gray's anatomy for students. Philadelphia: Churchill Livingstone; 2005. p. 331.

artery (IMA) via the marginal artery of Drummond. This anastomosis forms an important SMA-to-IMA collateral circulation that allows for the IMA to be sacrificed without colonic ischemia (Walker, 2009). However, despite the presence of this collateral circulation, injury to the SMA during left-sided retroperitoneal surgery may lead to severe bowel ischemia.

At L1, the paired renal arteries are the next branch of the aorta (Fig. 33-29 on the Expert Consult website). The inferior adrenal arteries branch off the renal arteries to supply the ipsilateral adrenal gland. There is considerable variation in the location, size, and number of renal arteries, with one quarter of cases manifesting with supernumerary renal arteries, which are more common on the right. The specific anatomic variations are discussed in depth in Chapter 42.

The gonadal arteries are the next paired branch of the aorta, typically arising anterolaterally from the aorta below the renal arteries. They may emerge from the renal artery in some variations, in which case they course with the gonadal vein. In males, the gonadal arteries are called the testicular arteries, and in females, they are called the ovarian arteries. The testicular arteries typically run anterior to the psoas, IVC, genitofemoral nerve, and ipsilateral ureter as they travel toward the internal inguinal ring.

The ovarian arteries arise from the anterolateral aspect of the aorta below the renal arteries. They travel anterior to the ureter and course medially as they pass through the infundibulopelvic ligament (suspensory ligament of the ovary) to the ovary. There are extensive collaterals to the gonads in both sexes, allowing for ligation of the testicular and ovarian arteries without gonadal ischemia.

The paired lumbar arteries arise posteriorly, adjacent to the bodies of the upper four lumbar vertebrae. They supply the posterior body wall and spine. In some instances, a fifth pair of lumbar arteries is present, arising from the middle sacral artery.

The IMA arises from the anterior aorta in the midline at the level of L3-L4 and supplies the colon from the splenic flexure to the upper rectum. The branches of the IMA are the left colic, sigmoid, and superior hemorrhoidal (rectal) arteries. The sigmoid artery branches into two to three inferior left colic arteries. As previously mentioned, the colonic branches of the IMA anastomose with the SMA via the marginal artery of Drummond and preclude colonic ischemia with IMA ligation. The superior hemorrhoidal artery has collateral circulation with the inferior and middle hemorrhoidal arteries, which branch off the internal iliac arteries. These collaterals provide blood supply to the rectum and prevent ischemia during IMA ligation.

Before bifurcation, the median sacral (middle sacral) artery arises from the posterior aspect of the aorta and courses over the fifth lumbar vertebra and sacrum. This vessel may be sacrificed if necessary without end-organ ischemia. At the fourth lumbar vertebra, the aorta bifurcates to form the common iliac arteries. No named branches are given off as these arteries enter the pelvis and divide to form the internal and external iliac arteries.

The ureter has a variable arterial supply that changes proximally and distally. Most often, the renal artery supplies the proximal ureter, and the internal iliac artery including its branches, the superior and inferior vesical arteries, supply the distal ureter. The middle ureter is typically supplied by the aorta; however, it may also be supplied by the common iliac, gonadal, uterine, middle rectal, and vaginal arteries. In general, the abdominal (proximal) ureter receives its blood supply medially, and the pelvic (distal) ureter receives its blood supply from a lateral direction.

Venous System

Although not as well defined, the layers of the venous system are similar to that of the arterial system. The layers from innermost to outermost are the intima, internal elastic lamina, media, external elastic lamina, and adventitia. As in the arterial system, the intima is composed of a layer of endothelial cells with subendothelial connective tissue. In the venous system, the internal and external elastic laminae are often poorly defined even in larger caliber vessels. The media layer of veins is significantly smaller than that of arteries and contains less vascular smooth muscle. Conversely, the venous adventitia is larger than the venous media and functions similar to the adventitia of the arterial system.

The venous system also differs from the arterial system with the presence of valves that prevent retrograde flow. These valves are typically bicuspid and they function to maintain the full venous blood flow toward the heart.

The major retroperitoneal venous structure is the IVC, formed from the confluence of the common iliac veins, inferior and to the right of the aortic bifurcation (see Fig. 33-27). The IVC ascends anterior to the vertebral bodies and to the right of the aorta through the retroperitoneum (Figs. 33-30 and 33-31 on the Expert Consult website). The infrarenal portion runs parallel and inferior to the aorta. On its ascent, the IVC becomes more anterior, and at the level of the diaphragm the great vessels are separated by the right crus of the diaphragm. The IVC then enters the thorax through the central tendon of the diaphragm at the level of T8 and drains into the inferior aspect of the right atrium.

Figure 33-29. Magnetic resonance angiogram, transverse section, right and left renal arteries arising from the aorta and supplying the kidneys. (From MacLennan GT. *Hinman's atlas of urosurgical anatomy*. 2nd ed. Philadelphia: Saunders; 2012.)

Figure 33-31. Intraoperative photograph of inferior vena cava and its tributaries. (From MacLennan GT. *Hinman's atlas of urosurgical anatomy*. 2nd ed. Philadelphia: Saunders; 2012.)

Figure 33-30. Radiograph showing inferior vena cava and its tributaries. (From MacLennan GT. *Hinman's atlas of urosurgical anatomy*. 2nd ed. Philadelphia: Saunders; 2012.)

The venous system is more variable than the arterial system; however, many venous structures run parallel with their arterial equivalent. The **median (middle) sacral vein** runs with its respective artery and typically drains into the left common iliac vein; however, it may enter into the angle created by convergence of the two common iliac veins. Avoiding these veins during fixation of the proximal limb of mesh during sacral colpopexy procedures is critical.

The ascending lumbar veins drain the posterior abdominal wall and run posterior to the psoas muscle and lateral to the spinal column (Fig. 33-32 on the Expert Consult website). They connect with the ipsilateral lumbar veins, which are variable in number and location compared with their arterial equivalents. These veins may assume a plexiform arrangement anterior to the vertebral bodies. As the ascending lumbar veins enter the thorax, they become the hemiazygos vein on the left and the azygos vein on the right.

In males, the gonadal veins (testicular veins) receive drainage from the pampiniform plexus, which is the venous complex that emerges from the testes. The testicular veins ascend through the retroperitoneum medially, running lateral to the respective artery and anterior to the ipsilateral ureter. The left testicular vein typically enters the inferior aspect of the left renal vein at a right angle; however, it may enter the IVC directly. The right testicular vein typically enters into the right anterolateral aspect of the IVC; however, it may enter into the right renal vein in 10% of cases. **These anatomic differences have clinical significance because the increased length and perpendicular entry of the left testicular vein into the left renal vein may account for the increased incidence of left-sided varicoceles.** This anatomic configuration may result in some element of increased back pressure in the left testicular vein compared with the right side. With the relative rarity of unilateral right-sided varicocele, a sudden-onset right varicocele should increase suspicion for a renal or retroperitoneal malignancy causing obstruction and poor venous outflow (e.g., right side renal cell cancer with venous thrombus). This clinical scenario should warrant retroperitoneal imaging to rule out malignancy.

The ovarian veins receive drainage from the pampiniform plexus adjacent to the ovarian hilum and travel through the infundibulopelvic ligament. As with the gonadal veins in males, the left ovarian vein enters the left renal vein, and the right ovarian vein empties into the anterolateral wall of the vena cava.

The renal veins course anteriorly to the renal arteries and empty into the lateral aspects of the vena cava at the level of L1. The right and left renal veins differ in length and tributaries with the right being shorter and typically having no tributaries. In rare cases, the right gonadal vein or a lumbar vein may empty into the right renal vein. In one sixth of cases, the renal vein is duplicated on the right side. The left renal vein is longer and typically receives the left gonadal vein at its caudal margin. At least one lumbar vein enters the left renal vein at or near the ostia of the gonadal vein. **The left adrenal vein is situated at the superior margin of the renal vein and in most patients inserts into the renal vein just medial to the gonadal vein.** The left adrenal vein occasionally is joined by the left inferior phrenic vein. The right adrenal vein is short, is single in number, has no tributaries, and drains directly into the posterolateral aspect of the vena cava. Although variable, the right inferior phrenic vein also typically drains into the superior portion of the IVC.

The gastrointestinal venous drainage does not mirror the arterial system as directly as the aforementioned venous structures. The portal venous system receives venous blood from the bowel, spleen, pancreas, and gallbladder to be emptied into the liver (Fig. 33-33 on the Expert Consult website). The superior mesenteric vein (SMV) receives venous drainage from the small intestine and the large intestine proximal to the splenic flexure. Tributaries of the SMV include the right gastro-omental, anterior and posterior inferior pancreaticoduodenal, jejunal, ileal, ileocolic, right colic, and middle colic veins. The SMV is joined by the splenic vein to form the portal vein. The tributaries of the splenic vein are the short gastric, left gastro-omental, pancreatic, and typically inferior mesenteric veins. The inferior mesenteric vein receives the venous

drainage from the colon distal to the splenic flexure. The portal vein splits into right and left branches, and the venous blood enters the endothelial lined hepatic sinusoids. After passing through these sinusoids, the venous blood leaves the liver through the hepatic veins, which enter the anterior aspect of the IVC before it crosses the diaphragm into the thorax. There are two groups of hepatic veins: the upper group, typically larger in caliber, and the lower group, which are typically smaller. **Occlusion of these hepatic veins can lead to Budd-Chiari syndrome, which is a form of progressive liver failure that often manifests rapidly with jaundice, ascites, abdominal pain, and hepatomegaly.**

LYMPHATIC SYSTEM

The lymphatic channels line tissue spaces and transport lymph to specialized areas of lymphoid tissue called lymph nodes. **The nodes typically have multiple afferent lymphatics and a single efferent lymphatic that drains into larger lymphatic vessels. Lymph generally flows cephalad from right to left until it returns to the venous circulation at the left innominate (brachiocephalic) vein.** Lymphatic fluid from the head, neck, right thorax, right arm, and right heart drains into the right innominate vein.

The lymphatic fluid from the pelvis and lower extremities drains into the internal iliac, external iliac, common iliac, obturator, and sacral nodes. These nodal regions then drain cephalad toward the lumbar nodes, whose efferent lymphatics form the lumbar trunks (Parker, 1935). The lumbar nodes are of considerable interest to the urologist because they provide the primary lymphatic drainage for structures supplied by lateral aortic arterial branches: the kidneys, adrenals, ureters, and gonads (Fig. 33-34). **For anatomic classification, three groups of lumbar nodes can be defined: left lumbar (aortic), interaortocaval (interaortocaval), and right lumbar (caval) nodal groups.**

The left lumbar group includes the preaortic, left para-aortic (periaortic), and retroaortic nodes. The preaortic nodes are located anterior to the abdominal aorta, around the major anterior arterial branches that supply the gastrointestinal tract. The celiac, superior mesenteric, and inferior mesenteric nodes receive lymphatic drainage based on the anatomy of the similarly named arteries that supply the corresponding abdominal viscera. The efferents of these lymphatics coalesce to form the intestinal trunk. The left para-aortic region includes the nodes lateral to the midline of the aorta and medial to the left ureter. The retroaortic nodes are variably present and located between the aorta and vertebrae. The interaortocaval nodal group extends from the midline of the IVC to the midline of the aorta.

The right lumbar group includes the precaval, right paracaval, and retrocaval nodes. The precaval nodes are located on the anterior wall of the IVC. The right paracaval region includes the area lateral to the midline of the IVC, extending to the right ureter. The retrocaval nodes are present between the vena cava and the psoas muscle.

The testes are significant because they are embryologically retroperitoneal and have retroperitoneal blood supply and primary lymphatic drainage. When practically discussing testis malignancy, the three significant nodal regions are the left para-aortic, interaortocaval, and right paracaval. Elegant studies of early metastasis demonstrated the drainage pattern of the testes. **The left testis drains to the left para-aortic nodes with some drainage to the interaortocaval nodes.** There is no significant drainage to the right paracaval nodes, which is consistent with the general direction of lymphatic flow from right to left. **The right testis drains primarily to the interaortocaval nodes with some drainage to the right paracaval nodes. The left para-aortic region receives a small but appreciable amount of lymphatic drainage from the right testis, consistent with the aforementioned right-to-left flow.**

The efferent lymphatics of the lateral lumbar nodes coalesce to form the right and left lumbar trunks. Posterior to the right side of the abdominal aorta and anterior to the L1 and L2 vertebrae, these trunks come together at a saccular dilated structure known as the

cisterna chyli. This marks the beginning of the **thoracic duct**, which runs cephalad posterior to the aorta and empties into the left innominate vein.

NERVOUS STRUCTURES

The nervous structures of the retroperitoneum can be divided into the **autonomic nervous system** and the **somatic nervous system**. The autonomic system supplies efferent and afferent innervation to the abdominal viscera, blood vessels, and smooth muscle. The somatic system supplies efferent and afferent innervation to skeletal muscle, skin, and peritoneum.

Autonomic Nervous System

The general structure of the **autonomic nervous system** consists of two nerves with two cell bodies. The **preganglionic neuron** has a cell body within the central nervous system and an axon that extends into the peripheral nervous system, synapsing with another neuron within a ganglion. The second neuron is referred to as a **postganglionic neuron**, and its axon enters the structure in which it provides innervation. One caveat to this general structure is the neural anatomy of the adrenal gland. The **preganglionic fibers synapse directly with the cells of the adrenal medulla resulting in release of catecholamines**. The adrenal can be considered a specialized ganglion of the autonomic nervous system.

The autonomic system can be divided further into the **parasympathetic** and **sympathetic nervous systems**. The **parasympathetic nervous system** has craniosacral outflow because the preganglionic fibers originate from cranial nerves III, VII, IX, and X and from the ventral rami of the second, third, and fourth sacral nerves. The preganglionic fibers from S2-S4 form the pelvic splanchnic nerves, which provide parasympathetic innervation to the pelvic and abdominal viscera, which often contain the postganglionic parasympathetic fibers within their walls. The vagus nerve (cranial nerve X) also provides preganglionic parasympathetic fibers to the thoracic, abdominal, and pelvic viscera.

In contrast to the parasympathetic system, the preganglionic fibers of the **sympathetic nervous system** originate between the first thoracic and the second lumbar vertebral levels. These fibers exit the spinal cord from T1 to L2 through the ventral root and course through the corresponding spinal nerve and anterior rami into the ipsilateral sympathetic trunk (Fig. 33-35). The fibers then run medial to the psoas muscle along the anterolateral aspect of the spine. The **paired sympathetic trunks are in close proximity to the lumbar arteries and veins, which cross them perpendicularly**. The preganglionic fibers can synapse within the ganglia of the sympathetic trunk and send forth postganglionic fibers to the body wall and lower extremities. The preganglionic fibers also may leave the trunk as splanchnic nerves to synapse with the ganglia of the autonomic plexuses of the aorta (Fig. 33-36).

The first and largest of these plexuses is the celiac plexus, which contains paired ganglia that lie lateral to the celiac artery. Much of the autonomic innervation to the kidney, adrenal, renal

Figure 33-35. Sympathetic chain and splanchnic nerves. (From Drake RL, Vogl AW, Mitchell AWM. *Gray's anatomy for students*. 2nd ed. Philadelphia: Churchill Livingstone; 2010.)

pelvis, and ureter runs through this plexus. Some of the autonomic innervation for the testes passes through this plexus and travels caudally with the testicular artery. The renal autonomic plexus is continuous with the celiac plexus and forms adjacent to the renal arteries. It contains the aorticorenal ganglion, which is an inferior extension of the celiac ganglion.

Much of the sympathetic innervation to the pelvic viscera travels through the superior and inferior hypogastric plexuses, which are contiguous. The superior hypogastric plexus originates at the caudal extent of the abdominal aorta and extends to the anterior surface of the fifth lumbar vertebra. **Extensive retroperitoneal dissection that causes disruption of these plexuses may result in loss of seminal vesicle emission or failure of bladder neck closure resulting in retrograde ejaculation.**

Confusion may arise with the term *splanchnic* used for nerves of both the parasympathetic and the sympathetic systems (see Fig. 33-35). For clarification, the thoracic splanchnics (greater, lesser, and least), lumbar splanchnics, and sacral splanchnics carry sympathetic fibers from the paired sympathetic trunks to the autonomic plexuses, whereas the pelvic splanchnics carry parasympathetic fibers from the sacral outflow.

Somatic Nervous System

The somatic sensory and motor nerves of the lower abdomen and lower extremities originate in the retroperitoneum. They form the lumbosacral plexus from the anterior rami of the lumbar and sacral nerves along with T12 (Fig. 33-37 on the Expert Consult website). The nerves arising from this plexus are in close proximity to the psoas muscle, with the superior nerves piercing the muscle, while the inferior nerves travel medial to the muscle body (Fig. 33-38). This plexus provides the cutaneous sensory innervation to the lower extremities (Fig. 33-39 and Table 33-4).

The **subcostal nerve** is an extension of the 12th thoracic nerve and runs inferior to the 12th rib. The **ilioinguinal and iliohypogastric nerves** arise from the anterior ramus of L1. These three nerves run laterally over the anterior aspect of the quadratus lumborum and travel through the transversus abdominis to run deep to the internal oblique muscle. They provide innervation to the muscles of the abdominal wall and sensory innervation to the posterolateral gluteal skin, upper medial thigh, and genitalia.

The **genitofemoral nerve** originates from L1 and L2 and courses anterior and parallel to the psoas muscle. The nerve typically divides near the level of the inguinal ligament. The **femoral branch** passes under the inguinal ligament and enters the femoral sheath to supply sensation to the upper anterior thigh. The **genital branch** enters the inguinal canal at the deep internal ring to provide motor innervation to the cremaster muscle. This motor component allows for contraction of the muscle during the cremasteric reflex. In addition to the motor component, the genital branch supplies sensation to the anterior scrotum in males and the mons pubis and labium majus in females. The genitofemoral nerve may be injured during a psoas hitch procedure (suture placement) and laparoscopic varicocelectomy (ligation). The **lateral cutaneous nerve of the thigh** (lateral femoral cutaneous nerve) arises from L2 and L3 and provides sensory innervation to the anterior and lateral thigh.

The **obturator nerve** originates from the anterior rami of L2-L4 posterior to the psoas muscle and courses inferiorly to the obturator canal. The function of the obturator nerve includes **hip adduction via motor innervation to the medial thigh compartment, which is of clinical significance during lateral transurethral resection and pelvic lymph node dissection.** Electrocautery employed during a transurethral resection of bladder tumor (TURBT) procedure may result in obturator nerve stimulation with

TABLE 33-4 Branches of the Lumbosacral Plexus

BRANCH	ORIGIN	SPINAL SEGMENTS	MOTOR FUNCTION	SENSORY FUNCTION
Subcostal	Anterior ramus T12	T12	Muscles of abdominal wall	Skin over hip
Iliohypogastric	Anterior ramus L1	L1	Internal oblique and transversus abdominis	Posterolateral gluteal skin and skin in pubic region
Ilioinguinal	Anterior ramus L1	L1	Internal oblique and transversus abdominis	Skin in upper medial thigh and the skin over either the root of the penis and anterior scrotum or the mons pubis and labium majus
Genitofemoral	Anterior rami L1 and L2	L1, L2	Genital branch: male cremasteric muscle	Genital branch: skin of anterior scrotum or skin of mons pubis and labium majus Femoral branch: skin of upper anterior thigh
Lateral cutaneous nerve of the thigh	Anterior rami L2 and L3	L2, L3	None	Skin on anterior and lateral thigh to the knee
Obturator	Anterior rami L2-L4	L2-L4	Obturator externus, pectineus, and muscles in medial compartment of thigh	Skin on medial aspect of thigh
Femoral	Anterior rami L2-L4	L2-L4	Iliacus, pectineus, and muscles in anterior compartment of thigh	Skin on anterior thigh and medial surface of leg

Modified from Drake RL, Vogl AW, Mitchell AWM. *Gray's anatomy for students*. Philadelphia: Churchill Livingstone; 2005.

subsequent rapid, forceful hip adduction. If this potential event is not anticipated and accounted for, severe bladder perforation may occur.

With its origin from the anterior rami of L2-L4, the **femoral nerve** provides efferent motor input to the muscles of the anterior thigh as well as the iliacus and pectineus, which are responsible for knee extension and hip flexion, respectively. The femoral nerve also gives sensory innervation to the skin over the anterior medial lower extremity. Compression of the femoral nerve may occur intraoperatively with placement of retractor blades inferolaterally against the inguinal ligament. Compression injury may result in a motor palsy to the quadriceps muscle, impairing extension at the knee.

Additionally, a stretch injury to the femoral nerve may occur with prolonged hip flexion in low lithotomy position used during minimally invasive pelvic surgery.

The **sciatic nerve** receives input from L4-S3 and provides the bulk of motor and sensory input to the lower extremities, including motor innervation to the posterior thigh compartment and all muscles in the leg and foot. Injury to this nerve may occur secondary to prolonged hip hyperflexion used during a high lithotomy position for vaginal and urethral procedures.

KEY POINTS

- The retroperitoneum is contained anteriorly by the posterior reflection of the peritoneum, posteriorly by the abdominal wall, cranially by the diaphragm, and caudally by the extraperitoneal pelvic structures.
- The lumbodorsal fascia merges anterolaterally with the transversus abdominis muscle and is composed of three layers that cover the posterior abdominal wall musculature.
- The anterior and posterior laminae of Gerota fascia form the boundaries of the perirenal space, which has a conelike shape that is open caudally in the extraperitoneal pelvis.
- The retroperitoneal gastrointestinal structures are the pancreas, the second and third portions of the duodenum, the ascending colon, and the descending colon.
- The renal hila are at the level of L1, and the renal veins are anterior to the renal arteries.
- The lymph of the left testis drains to the left para-aortic nodes with some to the interaortocaval nodes, and the right testis drains primarily to the interaortocaval nodes with some to the right paracaval nodes and a small amount to the left para-aortic region. This drainage is consistent with global lymphatic flow from right to left.
- The parasympathetic autonomic nervous system has craniosacral outflow and the postganglionic fibers are often contained within the walls of the innervated viscera.
- The preganglionic sympathetic nervous system fibers exit from the spinal cord from T1 to L2 and may synapse within the sympathetic trunk or within the autonomic plexuses.
- The somatic nervous system provides sensory and motor innervation to the pelvis and lower extremities through the lumbosacral plexus.

Germ Cell Tumors

Non-Germ Cell Tumors

Neoplasms of the testis constitute a morphologically and clinically diverse group of tumors, of which more than 95% are germ cell tumors (GCTs). GCTs are broadly categorized as seminoma and nonseminoma germ cell tumor (NSGCT) because of differences in natural history and treatment. GCT is a relatively rare malignancy, accounting for 1% to 2% of cancers among men in the United States. Approximately 95% of GCTs arise in the testis, and 5% are extragonadal in origin. With the development of cisplatin-based chemotherapy and the integration of surgery, GCTs have become a model of a curable neoplasm and serve as a paradigm for multidisciplinary treatment of cancer (Einhorn, 1981). In the era before cisplatin-based chemotherapy, the cure rate for patients with advanced GCT was 5% to 10%. At the present time, the long-term survival for men with metastatic GCT is 80% to 90%. With the successful cure of patients, an important treatment objective is minimizing treatment-related toxicity without compromising curability. Mortality from GCT is due to inherent resistance to cisplatin chemotherapy and the failure to eradicate fully residual disease elements in the early course of therapy.

Non-GCT tumors of the testis are rare and include sex cord-stromal tumors, lymphoid and hematopoietic tumors, tumors of the collecting duct and rete testis, and tumors of the testicular adnexa. A classification of testis neoplasms is presented in Box 34-1.

GERM CELL TUMORS

Epidemiology

In 2014, an estimated 8820 men were expected to develop testis cancer in the United States, and 380 were expected to die from this disease (Siegel et al, 2014). In the United States, testis cancer is the most common malignancy among men 20 to 40 years old and the second most common cancer after leukemia among adolescent boys and young men 15 to 19 years old (Horner et al, 2009). Testis tumors have three age peaks: infancy, age 30 to 34 years, and approximately age 60. The incidence of bilateral GCT is approximately 2.5% (0.6% risk of synchronous and 1.9% risk of metachronous contralateral tumors) (Fossa et al, 2005).

The incidence of testis cancer varies significantly according to geographic region. Rates are highest in Scandinavia, Western Europe, and Australia–New Zealand; intermediate in the United States and United Kingdom; and lowest in Africa and Asia (Weijl et al, 2000). The incidence of testis cancer in the United States in non-Hispanic whites is five times higher than the incidence in blacks, four times higher than the incidence in Asians, and 78% higher than in Hispanics (Horner et al, 2009).

The incidence of GCT appears to be increasing worldwide (McKiernan et al, 1999; McGlynn et al, 2005; Purdue et al, 2005). In the United States, the age-adjusted incidence rate for adolescent boys and men 15 to 49 years old increased from 2.9 per 100,000 in 1975 to 5.1 per 100,000 in 2004 (Holmes et al, 2008). Over this time period, incidence rates increased substantially more for seminoma than NSGCT (McGlynn et al, 2005; Powles et al, 2005). A

Tumors of the Testicular Adnexa

stage migration of GCT has been observed in several countries partly secondary to increased awareness and earlier diagnosis. Between 1973 and 2001, the percentage of tumors diagnosed at a localized stage increased from 55% to 73% in the United States among white men. The stage distribution for African-American men remained stable during this time (McGlynn et al, 2005). Only about 10% to 30% of men present with distant metastatic disease. In the United Kingdom, the change in stage distribution over time is largely restricted to an increase in localized seminoma and a decrease in metastatic NSGCT; rates of localized NSGCT and metastatic seminoma are largely unchanged (McGlynn et al, 2005). At the present time, localized seminoma is the most common presentation of GCT, representing approximately 50% of all men with GCT (Powles et al, 2005).

Risk Factors

There are four well-established risk factors for testis cancer: cryptorchidism, family history of testis cancer, a personal history of testis cancer, and intratubular germ cell neoplasia (ITGCN). Infertile men also have a higher incidence of testis cancer. Numerous studies have reported that more recent increases in testis cancer incidence can be largely attributed to birth-cohort effects, which implies that diet and/or other environmental factors play a major role in GCT carcinogenesis (Liu et al, 1999; Huyghe et al, 2003; McGlynn et al, 2003; Richiardi et al, 2004; Bray et al, 2006; Verhoeven et al, 2008).

Men with cryptorchidism are four to six times more likely to have testis cancer diagnosed in the affected gonad, but the relative risk decreases to two to three times more likely if orchidopexy is performed before puberty (Dieckmann and Pichlmeier, 2004; Wood and Elder, 2009). A meta-analysis of cryptorchidism studies reported that the contralateral descended testis is also at slightly increased risk (relative risk 1.74 [95% confidence interval 1.01 to 2.98]) (Akre et al, 2009). Men with a first-degree relative with testis cancer have a substantially increased risk of testis cancer, and the median age at diagnosis in these men is 2 to 3 years younger than in the general population (Mai et al, 2009). A man's relative risk for testis cancer is 8 to 12 with an affected brother compared with 2 to 4 in men with an affected father (Westergaard et al, 1996; Sonneveld et al, 1999b; Hemminki and Chen, 2006). Men with a history of testis cancer have a 12-fold increased risk of developing GCT in the contralateral testis, but the 15-year cumulative incidence is only 2%.

Most GCTs arise from a precursor lesion, ITGCN (which is also referred to as carcinoma in situ). ITGCN is present in adjacent testicular parenchyma in 80% to 90% of cases of invasive GCT and is associated with a 50% risk of GCT within 5 years and 70% within 7 years (Skakkebaek et al, 1982; Dieckmann and Skakkebaek, 1999; Montironi, 2002). Of patients with GCT, 5% to 9% have ITGCN within the unaffected contralateral testis, although the incidence of contralateral ITGCN increases to about 36% in men with testicular atrophy or cryptorchidism (Dieckmann and

BOX 34-1 World Health Organization Classification of Testicular Tumors

Germ cell tumors	Lymphoid and hematopoietic tumors
Precursor lesions—intratubular malignant germ cells (carcinoma in situ)	Lymphoma
Tumors of one histologic type (pure forms)	Plasmacytoma
Seminoma	Leukemia
Variant—seminoma with syncytiotrophoblastic cells	Tumors of collecting ducts and rete
Spermatocytic seminoma	Adenoma
Variant—spermatocytic seminoma with sarcoma	Carcinoma
Embryonal carcinoma	Tumors of the tunica, epididymis, spermatic cord, supporting structures, and appendices
Yolk sac tumor	Adenomatoid tumor
Polyembryoma	Mesothelioma
Trophoblastic tumors	Benign
Choriocarcinoma	Malignant
Choriocarcinoma with other cell types	Adenoma
Placental site trophoblastic tumor	Carcinoma
Teratoma	Melanotic neuroectodermal
Mature teratoma	Desmoplastic small round cell tumor
Dermoid cyst	Soft-tissue tumors
Immature teratoma	Unclassified tumors
Teratoma with malignant areas	Secondary tumors
Tumors of more than one histologic type (mixed forms)—specify types and estimate percentage	Tumorlike lesions
Sex cord–gonadal stromal tumors	Nodules of immature tubules
Pure forms	Testicular lesions of adrenogenital syndrome
Leydig cell tumor	Testicular lesions of androgen-insensitivity syndrome
Sertoli cell tumor	Nodular precocious maturation
Large-cell calcifying Sertoli cell tumor	Specific orchitis
Lipid-rich Sertoli cell tumor	Nonspecific orchitis
Granulosa cell tumor	Granulomatous orchitis
Adult-type granulosa cell tumor	Malakoplakia
Juvenile-type granulosa cell tumor	Adrenal cortical rest
Tumors of thecoma/fibroma group	Fibromatous peritonitis
Incompletely differentiated sex cord–gonadal stromal tumors	Funiculitis
Mixed forms	Residue of meconium peritonitis
Unclassified forms	Sperm granuloma
Tumors containing germ cell and sex cord–gonadal stromal elements	Vasitis nodosa
Gonadoblastoma	Sclerosing lipogranuloma
Mixed germ cell and sex cord–gonadal stromal tumors, unclassified	Gonadal splenic fusion
Miscellaneous tumors	Mesonephric remnants
Carcinoid tumor	Endometriosis
Tumors of ovarian epithelial types	Epidermal cyst
	Cystic dysplasia
	Mesolithial cyst
	Others

Data from Vogelzang NJ, Scardino PT, Shipley WU, et al, editors. Genitourinary oncology. Philadelphia: Lippincott Williams & Wilkins; 1999.

Loy, 1996; Dieckmann and Skakkebaek, 1999). Gene expression profile analysis indicates that ITGCN develops before birth from an arrested gonocyte (Hussain et al, 2008; Sonne et al, 2009). In men with a history of GCT, the finding of testicular microlithiasis on ultrasound of the contralateral testis is associated with an increased risk of ITGCN (Karellas et al, 2007). However, the significance of microlithiasis in the general population is unclear; a study of 1500 Army volunteers found a 5.6% prevalence of microlithiasis, yet less than 2% of men with microlithiasis developed GCT within 5 years (DeCastro et al, 2008).

Pathogenesis and Biology

The carcinogenesis of GCTs is poorly understood (Looijenga et al, 2011; Turnbull and Rahman, 2011; Sheikine et al, 2012). As noted earlier, testicular GCTs develop from a precursor lesion,

ITGCN, which appears to develop from arrested primordial germ cells or gonocytes that failed to differentiate into prespermatogonia (Rajpert-de Meyts and Hoei-Hansen, 2007; Hussain et al, 2008; Looijenga et al, 2011). These cells are thought to lay dormant until after puberty, when they are stimulated by increased testosterone levels.

The increased incidence of testis cancer that started in the first half of the 20th century has been accompanied by an increased incidence of other male reproductive disorders, such as hypospadias, cryptorchidism, and subfertility (Rajpert-de Meyts and Hoei-Hansen, 2007; Sonne et al, 2008). These findings led to the hypothesis that testis cancer and these other disorders all resulted from a testicular dysgenesis syndrome, which resulted from environmental and/or lifestyle factors and genetic susceptibility. The specific environmental or lifestyle factors have not been defined. Increased prenatal estrogen exposure has been hypothesized as a

risk factor, but this is controversial (Martin et al, 2008). There is stronger evidence that reduction in androgen activity can result in features of testicular dysgenesis syndrome, including cryptorchidism, hypospadias, and impaired spermatogenesis, but a direct link between reduced androgen signaling and ITGCN remains hypothetical (Sonne et al, 2008; Hu et al, 2009).

Evidence of environmental and lifestyle factors contributing to testis cancer includes the rapid increase in its incidence and findings that risk of second-generation immigrants is similar to their country of birth. In addition, mothers of children with testis cancer (but not the patients with testis cancer themselves) have been found to have higher blood levels of certain organic pollutants compared with other mothers (Sonne et al, 2008). Evidence for genetic factors includes the clustering of testis cancer in some families; the extreme difference in the rate of testis cancer in black and white Americans; and the finding of susceptibility loci on chromosomes 5, 6, and 12 in case-control studies (Mai et al, 2009). In addition, specific polymorphisms of certain genes, including the gene encoding c-KIT ligand, have been associated with an increased risk of testis cancer (Blomberg Jensen et al, 2008; Kanetsky et al, 2009; Turnbull and Rahman, 2011; Sheikine et al, 2012). Gonocytes depend on KIT ligand for survival, and the gene for this protein is located on the short arm of chromosome 12. An increased number of copies of genetic material from the short arm of chromosome 12 is a universal finding in testicular and extragonadal germ cell tumors. Of GCTs, 70% to 80% have an extra copy of chromosome 12 in the form of an isochromosome 12p ([i(12p)]), whereas the remainder show gain of 12p sequences detectable with fluorescence in situ hybridization (Looijenga et al, 2003). A connection between mutations or polymorphisms in c-KIT ligand and GCT has biologic plausibility.

One of the most striking features of GCTs is their sensitivity to cisplatin-based chemotherapy, which enables cure in most patients with widely metastatic disease. The specific biologic basis of this acute vulnerability to chemotherapy is incompletely understood but is thought to derive from the close relationship between GCTs and embryonal stem cells and gonocytes, which have a low threshold for undergoing apoptosis in response to DNA damage (Mayer et al, 2003; Schmelz et al, 2010). Gene expression analysis has found an upregulation of numerous genes that facilitate apoptosis, including *FasL*, *TRAIL*, and *Bax*, whereas *BCL-2* is downregulated (Schmelz et al, 2010). Expression patterns of genes controlling the G₁/S-phase checkpoint in GCTs appear to promote induction of apoptosis (Schmelz et al, 2010). In addition, GCTs lack transporters to export cisplatin from the cell and have a reduced ability to repair cisplatin-induced DNA damage (Mayer et al, 2003). GCTs have high intrinsic levels of wild-type p53 protein (which plays a role in mediating cell cycle arrest and apoptosis), and p53 mutations in GCTs are rare, yet differences have not been consistently found in p53 status when comparing chemosensitive and chemoresistant GCTs (Burger et al, 1998; Houldsworth et al, 1998). Similarly, expression of the antiapoptotic protein BCL-2 is low in GCTs, but BCL-2 levels do not distinguish chemosensitive and chemoresistant cell lines (Mayer et al, 2003). A small fraction of GCTs are resistant to chemotherapy, and the basis of that resistance remains obscure (Veenstra and Vaughn, 2011). Impaired DNA mismatch repair and activating *BRAF* mutations have been associated with treatment failure (Honecker et al, 2009; Looijenga et al, 2011; Veenstra and Vaughn, 2011; Sheikine et al, 2012).

Approximately 5% of GCTs are extragonadal in origin and develop in midline anatomic locations (retroperitoneum and mediastinum are most common). There are two main competing theories regarding the pathogenesis of extragonadal GCTs. The first hypothesizes that they originate from germ cells that mistakenly migrated along the genital ridge and were able to survive in an extragonadal environment. The second theory proposes a reverse migration from the testis to extragonadal locations (Chaganti and Houldsworth, 2000).

Primary mediastinal NSGCTs differ in several ways from NSGCTs originating in the testis or retroperitoneum (Moran and Suster, 1997a; Moran et al, 1997a, 1997b; Moran and Suster, 1998).

First, they are less sensitive to chemotherapy and have a poor prognosis with a 5-year overall survival of about 45% (Bokemeyer et al, 2002b). Mediastinal NSGCTs are more likely to have yolk sac tumor components and to be associated with elevations in serum α -fetoprotein (AFP) (Moran et al, 1997a; Bokemeyer et al, 2002b; Kesler et al, 2008). They are also associated with Klinefelter syndrome and with hematologic malignancies that carry extra copies of the short arm of chromosome 12, as seen in adult GCT (Bokemeyer et al, 2002a; McKenney et al, 2007). In contrast, mediastinal seminomas have a prognosis similar to testicular seminomas, and mature teratomas of the mediastinum have low metastatic potential and can generally be cured surgically (Lewis et al, 1983; International Germ Cell Consensus Classification, 1997; Allen, 2002). Primary retroperitoneal GCTs are indistinguishable biologically from testicular GCTs and carry the same prognosis.

Histologic Classification

The histologic classification of GCTs is outlined in Box 34-2 (Sobin and Wittekind, 2002). GCTs are broadly classified as seminoma and NSGCT, and the relative distribution is 52% to 56% and 44% to 48%, respectively (McGlynn et al, 2005; Powles et al, 2005). NSGCTs include embryonal carcinoma (EC), yolk sac tumor, teratoma, and choriocarcinoma subtypes, occurring either alone as pure forms or in combination as mixed GCT with or without seminoma (Ulbright, 2005). Most NSGCTs are mixed tumors that are composed of two or more GCT subtypes. GCTs that contain both NSGCT subtypes and seminoma are classified as NSGCTs.

Intratubular Germ Cell Neoplasia

With the exception of spermatocytic seminoma, all adult invasive GCTs arise from ITGCN. ITGCN consists of undifferentiated germ cells that have the appearance of seminoma that are located basally within the seminiferous tubules. The tubule usually shows decreased or absent spermatogenesis, and normal constituents are replaced by ITGCN. The presence of ITGCN in an orchiectomy specimen in men with testis cancer does not have any prognostic implications with regard to the risk of relapse (von Eyben et al, 2004). ITGCN is much less frequent in GCTs in pediatric patients (Cheville, 1999).

BOX 34-2 World Health Organization Classification of Germ Cell Tumors

- Intratubular germ cell neoplasia
- Tumors of one histologic type (pure forms)
 - Seminoma
 - Seminoma with syncytiotrophoblastic cells
 - Spermatocytic seminoma
 - Embryonal carcinoma
 - Yolk sac tumor
 - Trophoblastic tumors
 - Choriocarcinoma
 - Trophoblastic neoplasms other than choriocarcinoma
 - Monophasic choriocarcinoma
 - Placental site trophoblastic tumor
 - Teratoma
 - Dermoid cyst
 - Monodermal teratoma
 - Teratoma with somatic type malignancy (malignant transformation)
- Tumors of more than one histologic subtype (mixed forms)

From Sobin LH, Wittekind CH. UICC: TNM classification of malignant tumors. 6th ed. New York: Wiley-Liss; 2002.

Seminoma

Seminoma is the most common type of GCT. On average, seminomas occur at an older average age than NSGCTs, with most cases diagnosed in the fourth or fifth decade of life (Cheville, 1999). Grossly, seminoma is a soft tan-to-white diffuse or multinodular mass (Fig. 34-1A). Necrosis may be present but is usually focal and

not as prominent as in other GCTs. Seminomas consist of a sheet-like arrangement of cells with polygonal nuclei and clear cytoplasm, with the cells divided into nests by fibrovascular septa that contain lymphocytes (Fig. 34-1B) (Ulbright, 2005). Syncytiotrophoblasts, which stain positive for human chorionic gonadotropin (hCG), can be identified in about 15% of cases but are of no clear prognostic significance (Cheville, 1999). Lymphocytic infiltrates and

Figure 34-1. A, Gross section of testis containing seminoma. B, Seminoma (hematoxylin-eosin [H&E] stain). C, Embryonal carcinoma (H&E stain). D, Choriocarcinoma (H&E stain). E, Yolk sac tumor (H&E stain). F, Teratoma (H&E stain).

granulomatous reactions are often seen, and seminomas appear to be associated with an increased incidence of sarcoidosis (Rayson et al, 1998; Tjan-Heijnen et al, 1998). Seminomas may be confused with solid-pattern EC, yolk sac tumor, or Sertoli cell tumors (Ulbright and Young, 2008). Although immunohistochemical staining has a limited role in diagnosing GCTs, seminomas are typically negative for CD30, positive for CD117, and strongly positive for placental alkaline phosphatase (PLAP). Anaplastic seminoma was a previously recognized subtype of seminoma, but this distinction is of no clear biologic or clinical significance and is no longer recognized. **Seminoma arises from ITGCN and is considered to be the common precursor for the other NSGCT subtypes (Ulbright, 2004).** This ability of seminoma to transform into NSGCT elements has important therapeutic implications for the management of seminoma (discussed later) (Ulbright, 2004).

Spermatocytic Seminoma

Spermatocytic seminoma is rare and accounts for less than 1% of GCTs. Although classified as a variant of seminoma, these tumors represent a distinct clinicopathologic entity from other GCTs. In contrast to other GCTs, spermatocytic seminomas do not arise from ITGCN, are not associated with a history of cryptorchidism or bilaterality, do not demonstrate i(12p), and do not occur as part of mixed GCTs (Ulbright, 2005). Histopathologically, they differ from seminoma in that they do not stain for PLAP or glycogen (periodic acid–Schiff stain); nuclei are round; minimal lymphocytic infiltration is present; and three distinct cell types are present, including small lymphocyte-like cells, medium-size cells with dense eosinophilic cytoplasm and a round nucleus, and large mononucleated or multinucleated cells (Aggarwal and Parwani, 2009). The peak incidence is the sixth decade of life (Eble, 1994; Chung et al, 2004a). It is a benign tumor (only three documented cases of metastases) and is almost always cured with orchiectomy (Chung et al, 2004a; Horn et al, 2011). An exception to this rule are the rare cases of spermatocytic seminoma with sarcoma, which exhibit elements of sarcomatous differentiation, and anaplastic variant of spermatocytic seminoma; both of these entities are associated with widely metastatic chemotherapy-resistant disease and poor prognosis (Dundr et al, 2007; Narang et al, 2012; Wetherell et al, 2013).

Embryonal Carcinoma

EC consists of undifferentiated malignant cells resembling primitive epithelial cells from early-stage embryos with crowded pleomorphic nuclei (Ulbright, 2005). Grossly, EC is a tan-to-yellow neoplasm that often exhibits large areas of hemorrhage and necrosis. The microscopic appearance of these tumors varies considerably, and they may grow in solid sheets or in papillary, glandular-alveolar, or tubular patterns (Fig. 34-1C). In some cases, syncytiotrophoblasts are identified. EC is an aggressive tumor associated with a high rate of metastasis, often in the context of normal serum tumor markers. EC is the most undifferentiated cell type of NSGCT, with totipotential capacity to differentiate to other NSGCT cell types (including teratoma) within the primary tumor or at metastatic sites. As discussed subsequently, the presence and proportion of EC have been associated with an increased risk of occult metastases in clinical stage (CS) I NSGCT. EC typically stains for AE1/AE3, PLAP, and OCT3/4 and does not stain for c-KIT.

Choriocarcinoma

Choriocarcinoma is a rare and aggressive tumor that typically manifests with extremely highly elevated serum hCG levels and disseminated disease. These tumors are typically deemed poor risk (stage IIIC) at diagnosis because of the serum hCG level and/or nonpulmonary organ metastases (Alvarado-Cabrero et al, 2014). **Choriocarcinoma commonly spreads by hematogenous routes,** and common sites of metastases include lungs, liver, and brain (Tinkle et al, 2001; Allen, 2002; Osada et al, 2004; Yokoi et al, 2008;

Alvarado-Cabrero et al, 2014). Microscopically, the tumor is composed of syncytiotrophoblasts and cytotrophoblasts, and the former stain positively for hCG (Fig. 34-1D) (Cheville, 1999). Seminoma and EC may also contain syncytiotrophoblasts. Areas of hemorrhage and necrosis are prominent. Similar to gestational trophoblastic disease, testicular choriocarcinoma is prone to hemorrhage, sometimes both spontaneously and immediately after chemotherapy is initiated, and such bleeding can be catastrophic, particularly when it occurs in the lungs or brain (Motzer et al, 1987; Yokoi et al, 2008; Kandori et al, 2010). In addition, choriocarcinomas are associated with hormonal disturbances, most likely as a result of highly elevated serum hCG. Stimulation of receptors for thyroid-stimulating hormone and luteinizing hormone by hCG (which shares an identical α subunit) can result in hyperthyroidism and elevated androgen production (Ulbright, 2005). Hyperprolactinemia also has been reported.

Yolk Sac Tumor

Pure yolk sac tumors (sometimes called endodermal sinus tumors) represent a very small fraction of adult gonadal and retroperitoneal GCTs but are more common in mediastinal and pediatric GCTs (Moran et al, 1997a; Moran and Suster, 1997b; Ross et al, 2002; Ulbright, 2005; Cao and Humphrey, 2011). Mixed GCTs often include elements of yolk sac tumor, which consists of a reticular network of medium-sized cuboidal cells with cytoplasmic and extracytoplasmic eosinophilic, hyaline-like globules (Epstein, 2010). Yolk sac tumors may grow in a glandular, papillary, or microcystic pattern. Schiller-Duval bodies, which resemble endodermal sinuses, are a characteristic feature and are seen in roughly half of cases (Fig. 34-1E). Cytoplasmic and extracellular eosinophilic hyaline globules are another characteristic histologic feature and can be present in 84% of cases. **Yolk sac tumors almost always produce AFP but not hCG.**

Teratoma

Teratomas are tumors that contain well-differentiated or incompletely differentiated elements of at least two of the three germ cell layers: endoderm, mesoderm, and ectoderm. Characteristically, all components are intermixed. Well-differentiated tumors are labeled mature teratomas, whereas tumors that are incompletely differentiated (i.e., similar to fetal or embryonal tissue) are labeled immature teratomas. **In adolescent boys and men, there is no clinical significance to the distinction between mature and immature teratomas, and histopathologists do not typically distinguish between the two entities.** Mature teratomas may include elements of mature bone, cartilage, teeth, hair, and squamous epithelium (a fact that most likely explains the name teratoma, which roughly means “monster tumor” in Greek) (Fig. 34-1F). The gross appearance of teratoma depends largely on the elements within it, with most tumors having solid and cystic areas. **Teratomas are generally associated with normal serum tumor markers, but they may cause mildly elevated serum AFP levels.** Approximately 47% of adult mixed GCTs contain teratoma; pure teratomas are uncommon (Leibovitch et al, 1995b; Simmonds et al, 1996).

In men, teratomas have a histologically benign appearance but are frequently found at metastatic sites in patients with advanced NSGCT. **Teratoma is resistant to chemotherapy.** Given its frequent presence at metastatic sites in advanced NSGCT, patients with residual masses after chemotherapy require consolidative surgical resection. The inherent chemoresistance of teratoma is a limitation to treatment strategies for NSGCT that use chemotherapy alone.

Despite their benign histologic appearance, teratomas contain many genetic abnormalities frequently found in malignant GCT elements, including aneuploidy, i(12p), and widely variable proliferative capacity (Castedo et al, 1989; Sella et al, 1991). Studies have also shown that cystic fluid from teratoma frequently contains hCG and AFP, confirming its malignant potential (Sella et al, 1991; Beck et al, 2004). The genetic instability of teratoma has

important clinical implications. Teratomas may grow uncontrollably, invade surrounding structures, and become unresectable (termed *growing teratoma syndrome*) (Logothetis et al, 1982). Rarely, teratoma may transform into a somatic malignancy, such as rhabdomyosarcoma, adenocarcinoma, or primitive neuroectodermal tumor (Little et al, 1994; Comiter et al, 1998; Motzer et al, 1998). These tumors are called teratoma with somatic-type malignancy or teratoma with malignant transformation. These tumors frequently have abnormalities of i(12p), indicating their origin from GCT. Malignant transformation is highly aggressive, resistant to conventional chemotherapy, and associated with a poor prognosis (Comiter, 1998; El Mesbahi et al, 2007). Lastly, unresected teratoma in patients with advanced NSGCT may result in late relapse (Sheinfeld, 2003). All of these events may result in death.

KEY POINTS: GERM CELL TUMORS

- GCT is the most common solid malignancy among men 20 to 40 years old.
- Bilateral GCT occurs in 2% of men. A metachronous lesion is the most common presentation.
- The incidence of GCT is highest in whites and lowest in African-Americans.
- Cryptorchidism, personal or family history of GCT, and ITGCN are known risk factors for GCT.
- Orchidopexy for cryptorchidism performed before puberty is associated with a decreased risk of GCT.
- Approximately 70% of GCTs have an extra copy of chromosome 12 or i(12p), and this genetic marker may be used in the histopathologic diagnosis of GCT and non-GCT somatic malignancy arising from malignant transformation of teratoma.
- Approximately 5% of GCTs originate at extragonadal sites, most commonly mediastinum and retroperitoneum. Primary mediastinal NSGCTs are associated with a poor prognosis.
- Teratoma is histologically benign. Teratoma at metastatic sites arises from differentiation of metastatic embryonal carcinoma.
- Teratoma is resistant to chemotherapy.
- Teratoma is histologically benign but genetically unstable. It has unpredictable biology. Although uncommon, teratoma has the capacity to grow rapidly or undergo malignant transformation of ectodermal, mesodermal, or endodermal elements to form a non-GCT somatic malignancy.

Initial Presentation

Signs and Symptoms

The most common presentation of testis cancer is a **painless testis mass**. Acute testicular pain is less common and is caused by rapid expansion of the testis secondary to intratumor hemorrhage or infarction caused by rapid tumor growth. Pain is more commonly associated with NSGCT because these tumors tend to be more vascular and exhibit more rapid growth compared with seminomas. Patients frequently report a history of testicular trauma; incidental trauma is likely responsible for bringing the testis mass to the patient's attention for the first time. Patients may also complain of vague scrotal discomfort or heaviness. **Regional or distant metastasis at diagnosis is present in approximately one third of cases of NSGCT and 15% of cases of pure seminoma, and symptoms related to metastatic disease are the presenting complaint in 10% to 20% of patients** (Sonneveld et al, 1999a; Enewold et al, 2011). Bulky retroperitoneal metastasis may cause a palpable mass, abdominal pain, flank pain secondary to ureteral obstruction, back pain owing to involvement of the psoas muscle or nerve roots, lower extremity swelling secondary to compression of the inferior vena cava, or gastrointestinal symptoms. Pulmonary

metastasis may manifest with dyspnea, chest pain, cough, or hemoptysis. Metastasis to supraclavicular lymph nodes may manifest as a neck mass. **Approximately 2% of men have gynecomastia**, resulting from elevated serum hCG levels, decreased androgen production, or increased estrogen levels (most commonly seen in men with Leydig cell tumors). **Although approximately two thirds of men with GCT have diminished fertility, it is an uncommon initial presentation.**

Physical Examination

The physician should carefully examine the affected and the normal contralateral testis, noting their relative size and consistency and palpating for any testicular or extratesticular masses. Atrophy of the affected or contralateral testis is common, particularly in patients with a history of cryptorchidism. Any firm area within the testis should be considered suspicious for malignancy and should prompt further investigations. A hydrocele may accompany a testis cancer and impair the examiner's ability to evaluate the testis. In this case, a scrotal ultrasound scan to evaluate the testis is warranted. The patient also should be examined for any evidence of palpable abdominal mass or pain, inguinal lymphadenopathy (particularly if he has had prior inguinal or scrotal surgery), gynecomastia, and supraclavicular lymphadenopathy. Auscultation of the chest for intrathoracic disease should be done.

Differential Diagnosis

The differential diagnosis of a testis mass includes epididymo-orchitis, torsion, hematoma, or paratesticular neoplasm (benign or malignant). Other diagnostic possibilities include hernia, varicocele, or spermatocele, although these usually can be distinguished from a testis mass by physical examination. **A firm intratesticular mass should be considered cancer until proved otherwise and should be evaluated further with a scrotal ultrasound scan. Patients with a presumptive diagnosis of epididymo-orchitis should be re-evaluated within 2 to 4 weeks of completion of an appropriate course of oral antibiotics.** A persistent mass or pain should be evaluated further with scrotal ultrasonography.

Diagnostic Delay

Diagnostic delay is a well-recognized phenomenon of this disease, with patients and physicians contributing to this delay. Patients with testis cancer are typically young and may be less inclined to seek medical evaluation for symptoms because of denial, ignorance, or limited access. **In prior studies, up to one third of testis tumors were initially misdiagnosed as epididymitis or hydrocele** (Bosl et al, 1981). For patients who present with signs or symptoms resulting from metastatic GCT, these may become the focus of the treating physician, who fails to diagnose GCT. These patients may be subjected to inappropriate treatment, diagnostic tests, and unnecessary surgery with subsequent delays in definitive therapy. Case reports describe patients undergoing exploratory laparotomy, neck dissection, or mastectomy for unsuspected metastatic GCT. The interval of delay is associated with advanced clinical stage, suboptimal response to chemotherapy, and diminished survival. **Moul and colleagues (1990) reported a decrease in survival in patients with GCT treated during the period 1970 to 1987 with a diagnostic delay greater than 16 weeks, although a significant survival difference was not observed among patients treated in the cisplatin era.** **Stephenson and coworkers (2004) reported a higher proportion of men requiring intensive chemotherapy (multiple regimens, high-dose chemotherapy, and salvage chemotherapy) among men with a treatment delay greater than 30 days owing to unnecessary exploratory laparotomy.**

Diagnostic delay can be avoided by efforts to improve patient and physician education. Physicians must consider the diagnosis of GCT in any adolescent boy or man from age 15 to 50 years with a firm testis mass, midline retroperitoneal mass, or mass in the left supraclavicular fossa.

Diagnostic Testing and Initial Management

Scrotal Ultrasonography

In men presenting with a testis mass, hydrocele, or unexplained scrotal symptoms or signs, scrotal ultrasonography should be considered an extension of the physical examination because it is widely available, inexpensive, and noninvasive. With high-frequency transducers (5 to 10 MHz), intratesticular lesions a few millimeters in size can be identified and readily distinguished from extratesticular pathology. On ultrasound scan, a typical GCT is hypoechoic, and two or more discrete lesions may be identified (Fig. 34-2). Heterogeneous echotexture within a lesion is more commonly associated with NSGCT because seminomas usually have a homogeneous echotexture. The presence of increased flow within the lesion on color Doppler sonography is suggestive of malignancy, although its absence does not exclude GCT. The association between testicular microlithiasis and GCT is not clearly defined, and this finding alone should not prompt further evaluation (DeCastro et al, 2008). Given the 2% incidence of bilateral GCT, both testes should be evaluated with ultrasonography, although bilateral tumors at diagnosis are rare (0.5% of all GCTs), and metachronous presentation is more common (Fossa et al, 2005).

In men with advanced GCT and a normal testicular examination, scrotal ultrasonography should be performed to rule out the presence of a small, impalpable scar or calcification, indicating a “burned-out” primary testis tumor. GCTs are among the most common neoplasms to undergo spontaneous regression, with seminoma being the most frequent subtype (Balzer and Ulbricht, 2006). Radical orchiectomy should be performed in patients with sonographic evidence of intratesticular lesions (discrete nodule, stellate scar, coarse calcification) because ITGCN and residual teratoma are frequently encountered. Men with advanced GCT with normal testes on physical examination and ultrasound scan are considered to have primary extragonadal GCT.

The presence of small (<10 mm), impalpable intratesticular lesions in the absence of disseminated GCT or elevated serum tumor markers represents a diagnostic dilemma. Most of these lesions are benign (testicular cysts, small infarcts, Leydig cell nodules, or small Leydig cell or Sertoli cell tumors), although 20% to 50% may represent small GCTs (usually seminomas) (Hindley et al, 2003; Connolly et al, 2006; Muller et al, 2006; Shilo et al, 2012). The risk of malignancy increases with the size of the lesion, from 50% for lesions less than 1 cm to 80% or more for lesions 1 to 2 cm (Carmignani et al, 2005). Management options include inguinal orchiectomy, testis-sparing surgery involving inguinal

exploration and excision (with frozen-section analysis to rule out GCT), and close observation with serial ultrasound scans (with exploration of growing lesions). Intraoperative ultrasonography is useful during surgical exploration of the testis to locate the lesion.

Serum Tumor Markers

Testis cancer is one of the few malignancies associated with serum tumor markers (lactate dehydrogenase [LDH], AFP, and hCG) that are essential in its diagnosis and management (Gilligan et al, 2010). Serum tumor marker levels should be obtained at diagnosis, after orchiectomy, to monitor for response to chemotherapy, and to monitor for relapse in patients on surveillance and after completion of therapy.

At diagnosis, AFP levels are elevated in 50% to 70% of low-stage (CS I, IIA, and IIB) NSGCT and 60% to 80% of advanced (CS IIC and III) NSGCT. EC and yolk sac tumors secrete AFP. Choriocarcinomas and seminomas do not produce AFP. Patients with pure seminoma in the primary tumor with an elevated serum AFP are considered to have NSGCT. The half-life of AFP is 5 to 7 days. AFP levels may also be increased in patients with hepatocellular carcinoma; cancers of the stomach, pancreas, biliary tract, and lung; nonmalignant liver disease (infectious, drug-induced, alcohol-induced, autoimmune); ataxic telangiectasia; and hereditary tyrosinemia.

hCG levels are elevated in 20% to 40% of low-stage NSGCT and 40% to 60% of advanced NSGCT. Approximately 15% of seminomas secrete hCG. hCG is also secreted by choriocarcinoma and EC. Levels greater than 5000 IU/L are usually associated with NSGCT. The half-life of hCG is 24 to 36 hours. hCG levels may be elevated in cancers of the liver, biliary tract, pancreas, stomach, lung, breast, kidney, and bladder. The α subunit of hCG is common to several pituitary tumors, and so immunoassays for hCG are directed at the β subunit. Cross-reactivity of the hCG assay with luteinizing hormone may cause false-positive hCG elevations in patients with primary hypogonadism. Elevated serum hCG results caused by hypogonadism normalize within 48 to 72 hours after administration of testosterone, and this can be done to distinguish between true-positive and false-positive hCG results. Marijuana use may also cause false-positive hCG results.

LDH levels are elevated in approximately 20% of low-stage GCT and 20% to 60% of advanced GCT. LDH is expressed in smooth, cardiac, and skeletal muscle. Lymphoma may also cause elevated LDH levels. Of the five isoenzymes of LDH, LDH-1 is the most frequently elevated isoenzyme in GCT. LDH-1 levels are correlated with the chromosome arm 12p copy number, which is frequently amplified in GCT. The magnitude of LDH elevation correlates with the bulk of disease. As a nonspecific marker for GCT, its main use is in the assessment of prognosis of GCT at diagnosis. The serum half-life of LDH is 24 hours.

Patients suspected to have a GCT should have blood drawn for serum AFP, hCG, and LDH before orchiectomy to aid in the diagnosis and to help interpret tumor marker levels after orchiectomy. For staging purposes, it is relevant to know whether serum tumor marker levels obtained before orchiectomy are declining after orchiectomy and, if so, how quickly. The results of serum tumor marker assays should not be used to guide decision making about whether or not to perform a radical orchiectomy because AFP or hCG levels in the normal range do not rule out GCT. A significantly elevated serum AFP can establish the diagnosis of NSGCT in a patient whose histopathologic diagnosis is pure seminoma because seminomas do not produce AFP. However, borderline-elevated values should be interpreted cautiously. In rare patients who present with a testis, retroperitoneal, or mediastinal primary tumor and whose disease burden has resulted in a need to start treatment very urgently, substantially elevated serum AFP and/or hCG may be considered sufficient for diagnosis of GCT. For such rare, medically unstable patients, treatment need not be delayed until histology results permit a tissue diagnosis. However, these patients should undergo radical orchiectomy after the completion of chemotherapy because the testis is a sanctuary site for

Figure 34-2. Sagittal view of ultrasound of left testis showing multi-nodular hypoechoic intratesticular lesion confirmed to be pure seminoma at orchiectomy.

malignant GCT owing to the blood-testis barrier, and the testis frequently contains residual invasive GCT, teratoma, or ITGCN (Geldart et al, 2002).

Radical Inguinal Orchiectomy

Patients suspected to have a testicular neoplasm should undergo a radical inguinal orchiectomy with removal of the tumor-bearing testicle and spermatic cord to the level of the internal inguinal ring. A trans-scrotal orchiectomy or biopsy is contraindicated because it leaves the inguinal portion of the spermatic cord intact and may alter the lymphatic drainage of the testis, increasing the risk of local recurrence and pelvic or inguinal lymph node metastasis. Because of the rapid growth of GCTs, orchiectomy should be performed in a timely manner; delays greater than 1 to 2 weeks should be avoided. Radical orchiectomy establishes the histologic diagnosis and primary T stage, provides important prognostic information from the tumor histology, and is curative in 80% to 85% of CS I seminoma and 70% to 80% of CS I NSGCT.

Histopathologic examination of the testis should identify the histologic type of the tumor (see Box 34-2) (Sobin and Wittekind, 2002), tumor size, multifocality, local tumor invasion (rete testis, tunica albuginea, tunica vaginalis, epididymis, spermatic cord, scrotum), primary T stage (Table 34-1) (Greene et al, 2002; Sobin and Wittekind, 2002), presence of ITGCN, invasion of blood or lymphatic vessels (termed *lymphovascular invasion*), and surgical margin status. For patients with mixed GCT, each individual tumor subtype should be identified including its relative proportion. Because of the relative rarity of GCT and the importance of primary tumor histology for treatment decision making, review of primary tumor specimens by experienced pathologists is recommended (Krege et al, 2008a, 2008b). In a randomized, multicenter clinical trial, 5 of 382 NSGCT specimens (1.3%) were reclassified as seminomas by centralized pathologic review (Albers et al, 2008).

Testis-Sparing Surgery

Testis-sparing surgery (or partial orchiectomy) is highly controversial and has no role in the treatment of a patient suspected to have a testicular neoplasm with a normal contralateral testis.

However, it may be considered for organ-confined tumors less than 2 to 3 cm in size (30% of testicular volume) in patients with synchronous bilateral tumors or tumor in a solitary testis with sufficient testicular androgen production. It may also be considered for suspected benign tumor or indeterminate lesion less than 3 cm when serum AFP, hCG, and LDH are normal because the incidence of benign histology is 80% (Giannarini et al, 2010). Testis-sparing surgery is seldom feasible for larger tumors (>3 cm) because a complete excision frequently leaves insufficient residual testicular parenchyma for preservation. When testis-sparing surgery is performed, intraoperative frozen-section analysis can distinguish between benign and malignant histology in most cases (Tokuc et al, 1992; Elert et al, 2002). Biopsy of the adjacent testicular parenchyma should be performed to rule out the presence of ITGCN. For patients with ITGCN, adjuvant radiotherapy to the residual testis using doses of 20 Gy or greater is usually sufficient to prevent the development of a GCT, while preserving Leydig cell function (and testicular androgen production). Radiation at these doses causes permanent sterility of the treated testis. Leydig cell function may decline over time, and 40% of men who receive radiation therapy require supplemental testosterone (Petersen et al, 2002). The German Testicular Cancer Study Group reported no cases of local recurrence over a median follow-up of 91 months in 46 patients with small, organ-confined tumors who underwent testis-sparing surgery and received adjuvant radiotherapy for ITGCN (Heidenreich et al, 2001). In contrast, recurrent testis cancer developed in four of five men who did not receive adjuvant radiotherapy. Adjuvant radiotherapy may be delayed after testis-sparing surgery if fathering a child is desired, although close follow-up is mandatory (Giannarini et al, 2010).

Contralateral Testis Biopsy

Of patients with GCT, 5% to 9% have ITGCN in the normal contralateral testis (Dieckmann and Skakkebaek, 1999). In patients with an atrophic testis, history of cryptorchidism, or age younger than 40 years, the prevalence of ITGCN in the contralateral testis has been reported to be 36% (Dieckmann and Loy, 1996). An open inguinal biopsy of the contralateral testis may be considered in patients with risk factors for ITGCN or patients with suspicious lesions on preoperative ultrasound scan (Motzer et al, 2006).

TABLE 34-1 TNM Staging of Testicular Tumor: American Joint Committee on Cancer and Union Internationale Contre le Cancer

PRIMARY TUMOR (T)*

The extent of primary tumor is usually classified after radical orchiectomy and, for this reason, a *pathologic* stage is assigned.

pTx	Primary tumor cannot be assessed
pT0	No evidence of primary tumor (e.g., histologic scar in testis)
pTis	Intratubular germ cell neoplasia (carcinoma in situ)
pT1	Tumor limited to testis and epididymis without vascular/lymphatic invasion; tumor may invade into tunica albuginea but not tunica vaginalis
pT2	Tumor limited to testis and epididymis with vascular/lymphatic invasion or tumor extending through tunica albuginea with involvement of tunica vaginalis
pT3	Tumor invades spermatic cord with or without vascular/lymphatic invasion
pT4	Tumor invades scrotum with or without vascular/lymphatic invasion

REGIONAL LYMPH NODES (N)

Clinical (as Determined by Noninvasive Staging)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis with lymph node mass ≤ 2 cm in greatest dimension; or multiple lymph nodes, none more than 2 cm in greatest dimension
N2	Metastasis with lymph node mass, >2 cm, but not more than 5 cm in greatest dimension; or multiple lymph nodes, any one mass >2 cm but not more than 5 cm in greatest dimension
N3	Metastasis with lymph node mass >5 cm in greatest dimension

Continued

TABLE 34-1 TNM Staging of Testicular Tumor: American Joint Committee on Cancer and Union Internationale Contre le Cancer—cont'd

Pathologic (pN) (as Determined by Pathologic Findings of RPLND without Prior Chemotherapy or Radiotherapy)				
pNX	Regional lymph nodes cannot be assessed			
pN0	No regional lymph node metastasis			
pN1	Metastasis with lymph node mass ≤2 cm in greatest dimension and ≤5 nodes positive, none more than 2 cm in greatest dimension			
pN2	Metastasis with lymph node mass >2 cm but not more than 5 cm in greatest dimension; or >5 nodes positive, none more than 5 cm; or evidence of extranodal extension of tumor			
pN3	Metastasis with lymph node mass >5 cm in greatest dimension			
DISTANT METASTASIS (M)				
MX	Distant metastasis cannot be assessed			
M0	No distant metastasis			
M1	Distant metastasis			
M1a	Nonregional nodal or pulmonary metastasis			
M1b	Distant metastasis at site other than nonregional lymph nodes or lung			
SERUM TUMOR MARKERS (S)				
SX	Marker studies unavailable or not performed			
S0	Marker study levels within normal limits			
S1	LDH <1.5 × N† and hCG (mIU/mL) <5000 and AFP (ng/mL) <1000			
S2	LDH 1.5-10 × N or hCG (mIU/mL) 5000-50,000 or AFP (ng/mL) 1000-10,000			
S3	LDH >10 × N or hCG (mIU/mL) >50,000 or AFP (ng/mL) >10,000

Suspected Extragenadal Germ Cell Tumor

Approximately 5% of GCTs are of extragenadal origin (Bokemeyer et al, 2002b). Of patients with metastatic GCT without a testis mass, only one third definitively have a primary extragenadal GCT; one third have ITGCN in the testis, and one third have sonographic evidence of a “burned-out” primary tumor (Scholz et al, 2002). GCT should be considered in any male under 40 years with a midline mass. The presence of elevated serum AFP and/or hCG with a normal testicular evaluation is sufficient for the diagnosis of GCT, and histologic confirmation by biopsy is unnecessary before starting treatment. In cases of normal serum tumor markers, a biopsy of the mass should be performed to confirm the diagnosis of GCT before beginning treatment. A biopsy specimen showing poorly differentiated carcinoma represents a diagnostic dilemma if a primary tumor site cannot be confirmed. In this scenario, the diagnosis of extragenadal GCT with malignant transformation may be considered and supported by the expression of i(12p) in biopsy specimens. Patients with suspected extragenadal GCT should undergo inguinal orchiectomy at some point during their treatment course if the pattern of metastasis is consistent with a right-sided or left-sided testicular primary tumor or if there is sonographic evidence of a “burned-out” primary tumor.

KEY POINTS: DIAGNOSIS AND INITIAL MANAGEMENT OF GERM CELL TUMOR

- A solid intratesticular mass in a postpubertal male patient should be considered a GCT until proved otherwise.
- With rare exceptions, inguinal orchiectomy with high ligation of the spermatic cord should be performed in men suspected to have GCT. Trans-scrotal orchiectomy and biopsy should be avoided.
- Testis-sparing surgery for GCT is a consideration in highly selected patients who have a small tumor in either a solitary testis or synchronous bilateral testis masses, in whom preservation of the affected testis would provide sufficient testicular androgen production.
- Diagnostic delay is common in GCTs, and approximately one third of cases are initially misdiagnosed.
- If serum tumor marker levels were elevated before orchiectomy, they should be measured after orchiectomy to determine if levels are declining, stable, or rising. Serum tumor marker levels obtained before orchiectomy should not be used in management decisions.

Clinical Staging

The prognosis of GCT and initial management decisions are dictated by CS of the disease, which is based on the histopathologic findings and pathologic stage of the primary tumor, serum tumor marker levels measured after orchiectomy, and the presence and extent of metastatic disease as determined by physical examination and staging imaging studies. In 1997, an international consensus classification for GCT was developed by the American Joint Committee on Cancer (AJCC) and Union Internationale Contre le Cancer (UICC) (see Table 34-1). The AJCC and UICC staging systems for GCT are unique because, for the first time, a serum tumor marker category (S) based on postorchiectomy AFP, hCG, and LDH levels is used to supplement the prognostic stages as defined by anatomic extent of disease. **The AJCC and UICC staging systems were updated in 2002, and the new systems consider the presence of LVI in the primary as pT2 in an otherwise organ-confined tumor. CS I is defined as disease clinically confined to the testis, CS II indicates the presence of regional (retroperitoneal) lymph node metastasis, and CS III represents nonregional lymph node and/or visceral metastasis.**

Staging Imaging Studies

GCT follows a predictable pattern of metastatic spread, which has contributed to its successful management. With the exception of choriocarcinoma, the most common route of disease dissemination is via lymphatic channels from the primary tumor to the retroperitoneal lymph nodes and subsequently to distant sites. Choriocarcinoma has a propensity for hematogenous dissemination. The retroperitoneum is the initial site of metastatic spread in 70% to 80% of patients with GCT. Detailed mapping studies from retroperitoneal lymph node dissection (RPLND) series have increased understanding of the testicular lymphatic drainage and identified the most likely sites of metastatic spread (Sheinfeld, 1994). For right testis tumors, the primary drainage site is the inter-aortocaval lymph nodes inferior to the renal vessels, followed by the paracaval and para-aortic nodes. The primary “landing zone” for left testis tumors is the para-aortic lymph nodes, followed by the inter-aortocaval nodes (Donohue et al, 1982). The pattern of lymph drainage in the retroperitoneum is from right to left. Contralateral spread from the primary “landing zone” is common with right-sided tumors but is rarely seen with left-sided tumors and usually is associated with bulky disease. More caudal deposits of metastatic disease usually reflect retrograde spread to distal iliac and inguinal lymph nodes secondary to large-volume disease and, more rarely, aberrant testicular lymphatic drainage. Retroperitoneal lymphatics drain into the cisterna chyli behind the right renal artery and right crus of the diaphragm. Retrocaval lymph node metastasis may be visible in patients with retroperitoneal disease. From there, lymphatic spread occurs via the thoracic duct to the posterior mediastinum and left supraclavicular fossa.

Clinical Staging of the Abdomen and Pelvis. All patients with GCT should undergo staging imaging studies of the abdomen and pelvis. Computed tomography (CT) imaging with oral and intravenous contrast material is the most effective, noninvasive means of staging the retroperitoneum and pelvis. CT imaging also provides a detailed anatomic assessment of the retroperitoneum to identify anatomic anomalies that may complicate subsequent RPLND, such as a circum-aortic or retro-aortic left renal vein, lower pole renal artery, or retrocaval right ureter. Magnetic resonance imaging is an alternative to CT, although it is associated with longer examination times, higher cost, and less availability.

Enlarged retroperitoneal lymph nodes are found on CT in approximately 10% to 20% of seminomas and 60% to 70% of NSGCTs. The retroperitoneum is the most difficult area to assign CS accurately. A consistent 25% to 35% rate of pathologically involved retroperitoneal lymph nodes has been reported for CS I NSGCT in the presence of a “normal” CT scan despite the improvements in CT imaging over the last four decades (Fernandez et al, 1994). There is no consensus regarding size criteria for retroperitoneal lymph nodes that constitutes a “normal” CT scan. A size cutoff of 10 mm is frequently used to identify enlarged lymph nodes, but false-negative rates up to 63% have been reported when this size criterion is used. Among patients with CS IIA and IIB disease, clinical overstaging by CT (i.e., pathologically negative lymph nodes at RPLND despite enlarged lymph nodes on CT) is reported in 12% to 40% of patients.

An understanding of the primary drainage sites for left-sided and right-sided tumors has led to efforts to increase the sensitivity of abdominopelvic CT imaging by decreasing the size criteria for clinically positive lymph nodes in the primary landing zone. Leibovitch and colleagues (1995a) showed that using a size cutoff of 4 mm in the primary landing zone and 10 mm outside this region was associated with sensitivity and specificity for pathologic stage II disease of 91% and 50%, respectively. In a similar study, Hilton and associates (1997) reported sensitivity and specificity of 93% and 58%, respectively, using a cutoff of 4 mm for lymph nodes in the primary landing zone that were anterior to a horizontal line bisecting the aorta. **Based on this evidence, retroperitoneal lymph nodes 5 to 9 mm in size in the primary landing zone should be viewed with suspicion for regional lymph node metastasis, particularly if they**

Figure 34-3. Postorchiectomy computed tomography image of the abdomen and pelvis in a patient with right testicular nonseminoma germ cell tumor showing a 7-mm lymph node in a primary landing zone. The lymph node was involved with teratoma at retroperitoneal lymph node dissection.

are anterior to the great vessels on transaxial images (Fig. 34-3). Because of the rapid growth of GCTs, it is advisable to base management decisions on CT imaging studies performed within 4 weeks of the initiation of treatment.

Malignant GCTs accumulate fluorodeoxyglucose (FDG), and several studies have investigated positron emission tomography with FDG (FDG-PET) in the staging of GCTs at diagnosis and assessing response after chemotherapy. Several small pilot studies suggested that FDG-PET can identify retroperitoneal metastasis in low-stage seminoma and NSGCT more precisely than CT (Albers et al, 1999). In a prospective trial of centrally reviewed FDG-PET studies in 111 contemporary patients with CS I NSGCT on surveillance, relapse was observed in 33 of 87 patients who were PET-negative with an estimated relapse-free rate of 63% (Huddart et al, 2007). The investigators concluded that FDG-PET is not sufficiently sensitive to stage CS I NSGCT accurately. *de Wit and colleagues* (2008) also reported that FDG-PET yielded only slightly better results than CT as a primary staging tool for low-stage NSGCT. **There is currently no role for FDG-PET in the routine evaluation of NSGCT and seminoma at the time of diagnosis.**

CS II disease is subclassified based on the size of regional lymph nodes as determined by abdominopelvic imaging into IIA (enlarged retroperitoneal lymph nodes ≤ 2 cm), IIB (enlarged retroperitoneal lymph nodes >2 cm but ≤ 5 cm), and IIC (enlarged lymph nodes >5 cm).

Pathologic Staging of the Abdomen and Pelvis. In selected European centers performing open RPLND and most laparoscopic RPLND series, RPLND is performed in patients with CS I or IIA NSGCT largely as a staging procedure without curative intent to identify the presence of regional lymph nodes and determine the need for subsequent chemotherapy (Nelson et al, 1999; Janetschek et al, 2000; Albers et al, 2003; Bhayani et al, 2003; Nielsen et al, 2007; Albers et al, 2008). Pathologic N stage differs from clinical N stage in that the former considers the number of lymph nodes involved: pN0, no regional lymph node metastasis; pN1, five or fewer lymph nodes involved, none larger than 2 cm; pN2, more than five lymph nodes involved and/or any lymph node 2 to 5 cm; pN3, any lymph node larger than 5 cm. In patients with pathologic stage II disease (pTany, pN1-3, M0), the risk of occult metastases (and relapse after RPLND) is closely related to the burden of regional lymph node metastasis (10% to 30% of pN1 vs. 50% to 80% for pN2-3). The pathologic N stage cannot be applied to RPLND specimens from patients who have received prior chemotherapy.

Chest Imaging

All patients with GCTs should undergo chest imaging before management decisions are made. Thoracic metastasis in the absence of retroperitoneal disease and/or elevated serum tumor markers is uncommon, particularly for seminomas. Routine chest CT imaging may be associated with a high rate of false-positive findings, which may complicate subsequent therapy (Horan et al, 2007). It is reasonable to obtain chest radiographs at the time of diagnosis as an initial staging study, and CT should be performed in patients with elevated serum tumor markers after orchiectomy, evidence of metastatic disease by physical examination or abdominopelvic CT imaging, or abnormal or equivocal findings on chest radiograph. It may be reasonable to order chest CT in patients with CS I NSGCT with evidence of LVI or EC predominance because some studies have reported a high rate of hematogenous metastasis to lung in the setting of a negative CT scan for retroperitoneal metastasis (Hermans et al, 2000; Sweeney et al, 2000). Mediastinal or hilar lymphadenopathy in the absence of retroperitoneal disease should raise the index of suspicion of non-GCT etiology such as lymphoma or sarcoidosis, and histologic confirmation of GCT by mediastinoscopy and biopsy should be performed before initiating systemic therapy (Hunt et al, 2009).

Visceral metastasis to bone and brain is uncommon in GCT in the absence of symptoms or other clinical indicators of disease. There is no role for routine bone scintigraphy or brain CT imaging at the time of diagnosis. A notable exception is brain CT imaging for patients with a highly elevated hCG ($>10,000$ mU/mL) because these levels are often associated with metastatic choriocarcinoma, which has a propensity for brain metastases.

Serum Tumor Markers

AFP, hCG, and LDH levels measured after orchiectomy are important for staging, prognosis, and treatment selection. All patients should have serum tumor markers drawn after orchiectomy to assess for appropriate decline according to half-life in patients with elevated levels before orchiectomy. Newly elevated and/or rising serum tumor marker levels after orchiectomy indicate the presence of metastatic disease, and these patients should receive induction chemotherapy. In the setting of a negative metastatic evaluation and slowly declining markers (i.e., not according to half-life), patients should be monitored closely and have levels checked periodically until the levels normalize or begin to rise. Stable AFP or hCG levels slightly above the normal range should be interpreted cautiously, and other causes for serum tumor marker elevation should be ruled out before management decisions are made. As with staging imaging studies, management decisions should be based on serum tumor marker levels measured within 4 weeks of the initiation of treatment.

Prognostic Classification of Advanced Germ Cell Tumors

An international, retrospective pooled analysis of 5202 patients with advanced NSGCT treated between 1975 and 1990 with platin-containing chemotherapy regimens (cisplatin or carboplatin) identified AFP, hCG, and LDH levels at the initiation of chemotherapy; the presence of nonpulmonary visceral metastasis; and primary mediastinal NSGCT as significant and independent prognostic factors for progression and survival (International Germ Cell Consensus Classification, 1997). In 660 patients with advanced seminoma, only the presence of nonpulmonary visceral metastasis was an important predictor of progression and survival (International Germ Cell Consensus Classification, 1997).

Based on these analyses, the International Germ Cell Cancer Collaborative Group (IGCCCG) risk classification for advanced GCT was developed (Table 34-2) (International Germ Cell Consensus Classification, 1997). The IGCCCG risk group should be determined for each patient with metastatic GCT, and this should be used to guide treatment decision making on the choice of chemotherapy (discussed later). This classification applies only to

TABLE 34-2 International Germ Cell Cancer Collaborative Group Risk Classification for Advanced Germ Cell Tumor

NONSEMINOMA	SEMINOMA
GOOD PROGNOSIS	
Testicular/retroperitoneal primary <i>and</i> No nonpulmonary visceral metastases <i>and</i> Good markers—all of: AFP <1000 ng/mL <i>and</i> hCG <5000 IU/L (1000 ng/mL) <i>and</i> LDH <1.5 × upper limit of normal (N) 56% of nonseminomas 5-year PFS 89% 5-year survival 92%	Any primary site <i>and</i> No nonpulmonary visceral metastases <i>and</i> Normal AFP, any hCG, any LDH 90% of seminomas 5-year PFS 82% 5-year survival 86%
INTERMEDIATE PROGNOSIS	
Testicular/retroperitoneal primary <i>and</i> No nonpulmonary visceral metastases <i>and</i> Intermediate markers—any of: AFP ≥1000–10,000 ng/mL <i>and</i> ≤10,000 ng/mL <i>or</i> hCG ≥5000–50,000 IU/L <i>and</i> ≤50,000 IU/L <i>or</i> LDH ≥1.5 × N <i>and</i> ≤10 × N 28% of nonseminomas 5-year PFS 75% 5-year survival 80%	Any primary site <i>and</i> Nonpulmonary visceral metastases <i>and</i> Normal AFP, any hCG, any LDH 10% of seminomas 5-year PFS 67% 5-year survival 72%
POOR PROGNOSIS	
Mediastinal primary <i>or</i> Nonpulmonary visceral metastases <i>or</i> Poor serum markers—any of: AFP >10,000 ng/mL <i>or</i> hCG >50,000 IU/L (10,000 ng/mL) <i>or</i> LDH >10 × upper limit of normal 16% of nonseminomas 5-year PFS 41% 5-year survival 48%	No patients classified as poor prognosis

AFP, α -fetoprotein; hCG, human chorionic gonadotropin; LDH, lactate dehydrogenase; PFS, progression-free survival.

From International Germ Cell Consensus Classification: a prognostic factor-based staging system for metastatic germ cell cancers. International Germ Cell Cancer Collaborative Group. *J Clin Oncol* 1997;15:594–603.

patients with advanced GCT at the time of diagnosis and is not applicable to patients with relapsed GCT. It is also based on the postorchietomy serum tumor marker levels at the start of chemotherapy, not levels measured before orchietomy.

According to IGCCCG criteria, approximately 56% of patients with advanced NSGCT are classified as good risk, 28% are classified as intermediate risk, and 16% are classified as poor risk, and the

5-year progression-free and overall survival rates for these patients are 89% and 92% (good risk), 75% and 80% (intermediate risk), and 41% and 48% (poor risk). There is no poor risk category for seminoma. Approximately 90% and 10% of patients with advanced seminoma are classified as good and intermediate risk by IGCCCG criteria, respectively, and the 5-year progression-free and overall survival rates for these patients are 82% and 86% (good risk) and 67% and 72% (intermediate risk). [Van Dijk and colleagues \(2006\)](#) published a meta-analysis of 10 studies of 1775 patients with NSGCT treated after 1989 and reported pooled 5-year survival estimates of 94%, 83%, and 71% for good-risk, intermediate-risk, and poor-risk patients by IGCCCG criteria. These results represent significantly improved survival compared with the original study (particularly for patients classified as poor risk) and are attributed to more effective therapy and more experience in treating patients with NSGCT.

The TNM system incorporates marker levels (S0-3) and nonpulmonary visceral metastasis in the staging of testis cancer. However, this system does not consider the differences in prognosis between seminomas and NSGCTs with nonpulmonary visceral metastasis. In the TNM system, both of these entities would be classified as stage IIIC, but IGCCCG would classify the former as intermediate risk and the latter as poor risk. The IGCCCG system is preferentially used for prognostic assessment and the selection of chemotherapy.

Sperm Cryopreservation

Although infertility is an uncommon presentation for GCT, up to 52% of men have oligospermia at diagnosis and 10% are azoospermic ([Williams et al, 2009a](#)). The limited data that exist suggest that roughly half of these men recover normospermia after orchietomy ([Carroll et al, 1987](#); [Jacobsen et al, 2001](#)). The germinal epithelium is exquisitely sensitive to platin-based chemotherapy and radiation therapy. Virtually all patients become azoospermic after chemotherapy, and 50% and 80% of patients with normal semen parameters at diagnosis return to these levels within 2 and 5 years, respectively ([Bokemeyer et al, 1996a](#); [Feldman et al, 2008](#)). Recovery of spermatogenesis after radiation therapy for seminoma may take to 2 to 3 years or longer ([Fossa et al, 1999b](#)). RPLND may result in ejaculatory dysfunction in 80% or more of patients undergoing a full, bilateral template dissection without nerve sparing. Most men are able to father children after standard chemotherapy for GCTs; radiotherapy appears to have a more deleterious effect on fertility than chemotherapy ([Huyghe et al, 2004](#)). Given the impact of treatments for testis cancer on fertility, men who are undecided or are planning future paternity are recommended to undergo sperm cryopreservation before treatment is initiated. Sperm banking can be done before or after radical orchietomy.

Treatment

Therapeutic Principles

The management of GCTs is governed by the potential for rapid growth and for cure in essentially all patients; this translates into a need for rapid diagnosis and staging and expeditious application of appropriate treatment so as not to have patients die unnecessarily or experience side effects from treatment that would not have been required with earlier diagnosis and proper management. After orchietomy, staging imaging studies, serum tumor marker status should be performed and treatment plans should be developed as rapidly as can be reasonably accomplished.

The probability of cure even in the presence of metastatic disease has led to an aggressive approach with regard to the administration of chemotherapy and the performance of surgery after chemotherapy to resect residual masses. Chemotherapy is generally administered regardless of low white blood cell counts or thrombocytopenia, and nephrotoxic chemotherapy (cisplatin) is often administered even in the presence of moderate to severe renal

KEY POINTS: CLINICAL STAGING

- Testicular GCT follows a predictable pattern of spread from the primary tumor to retroperitoneal lymph nodes and then to distant metastatic sites.
- The primary landing zone for left-sided tumors is the para-aortic and left renal hilar lymph nodes and for right-sided tumors is the inter-aortocaval and paracaval lymph nodes.
- CT imaging is the optimal modality for staging the retroperitoneum, although false-negative scans occur in 25% to 35% and 14% to 20% of patients with CS I NSGCT and seminoma, respectively, when a 1-cm cutoff is used.
- Chest radiograph and chest CT scan are acceptable staging modalities in the absence of retroperitoneal lymphadenopathy or elevated serum tumor marker levels.
- Increasing serum tumor marker levels after orchiectomy indicate the presence of metastatic GCT, and these patients should receive chemotherapy.
- The IGCCCG risk classification is used to evaluate the prognosis of patients with metastatic GCT and dictates the selection of chemotherapy. For NSGCT, IGCCCG risk is assigned based on postorchiectomy serum tumor marker levels, mediastinal primary tumor, and the presence of nonpulmonary visceral metastases. For seminoma, IGCCCG risk is assigned based on the presence of nonpulmonary visceral metastases only.
- Sperm cryopreservation should be offered to all patients before RPLND, chemotherapy, or radiation therapy because of the potential effects of these treatments on fertility.

insufficiency (Williams et al, 1987; Einhorn et al, 1989; Bajorin et al, 1993; Loehrer et al, 1995; Bokemeyer, et al, 1996b; Nichols et al, 1998; de Wit et al, 2001). Similarly, an aggressive surgical approach is taken to resect all sites of residual disease after chemotherapy for NSGCT even if this involves multiple anatomic sites. The young age and generally good health of patients with GCTs permits an aggressive treatment approach if needed.

Serum tumor markers strongly influence the management of GCTs, particularly NSGCTs. As discussed, **elevated serum AFP or hCG after orchiectomy indicates the presence of metastatic disease, and these patients are preferentially given chemotherapy.** For patients receiving chemotherapy, increasing serum tumor marker levels during or after therapy generally indicate refractory or relapsed disease, respectively. As discussed earlier, serum AFP, hCG, and LDH levels at the initiation of chemotherapy are important prognostic factors and influence the selection and duration of chemotherapy regimens (*International Germ Cell Consensus Classification, 1997*).

Testis cancer is a relatively rare disease, and general urologists and general oncologists do not typically treat a large volume of patients with GCTs. In addition, the treatment algorithms are complex and nuanced, and the data supporting certain treatments, such as RPLND, are based on data from a relatively small number of surgeons who have performed a large number of these operations (Donohue et al, 1993, 1995; Heidenreich et al, 2003; Stephenson, et al, 2005b; Williams et al, 2009b). Most urology residents in the United States complete their training having performed two or fewer RPLND procedures (Lowrance et al, 2007). Several studies reported improved survival when the treatment was provided at high-volume institutions (Aass et al, 1991; Harding et al, 1993; Feuer et al, 1994; Collette et al, 1999; Joudi and Konety, 2005; Suzumura et al, 2008). Whenever possible, patients with GCTs should be treated at high-volume centers, and RPLND should be performed by surgeons who are experienced with this operation.

Contrasting Seminoma and Nonseminoma Germ Cell Tumor

For treatment purposes, the distinction between seminoma and NSGCT is very important. Compared with NSGCT, seminoma has

a more favorable natural history. In general, seminoma tends to be less aggressive, to be diagnosed at an earlier stage, and to spread predictably along lymphatic channels to the retroperitoneum before spreading hematogenously to the lungs or other organs. **At diagnosis, the proportion of patients with CS I, II, and III disease is 85%, 10%, and 5% for seminoma and approximately 33%, 33%, and 33% for NSGCT (Powles et al, 2005).** Seminoma is also associated with a lower incidence of occult metastasis among patients with CS I (10% to 15% vs. 25% to 35% for NSGCT) and a lower risk of systemic relapse after treatment of the retroperitoneum (1% to 4% after radiotherapy for seminoma vs. 10% after RPLND for NSGCT), which has important implications for the use of chemotherapy. Seminoma is less likely to have elevated serum tumor markers, and serum tumor markers do not range as high as in NSGCT. Also, serum tumor markers are not used in the IGCCCG risk classification of seminoma.

Compared with NSGCT, **seminoma is exquisitely sensitive to radiation therapy and platin-based chemotherapy.** Substantially lower radiation doses are required to eradicate seminoma compared with other solid tumors. **Radiation therapy is a standard treatment option for CS I, IIA, and IIB seminoma but has no role in NSGCT,** with the exception of treatment for brain metastases. Seminoma accounts for only 10% of advanced GCT cases despite the fact that it accounts for 52% to 56% of all GCTs. A poor prognosis IGCCCG risk category does not exist for advanced seminoma, and greater than 90% of metastatic cases are classified as good risk (compared with 56% for NSGCT) (*International Germ Cell Consensus Classification, 1997*). **The risk of teratoma at metastatic sites is generally not a consideration for advanced seminoma, which has important implications for the management of residual masses after chemotherapy.** However, the potential for seminoma to transform into NSGCT elements is an important consideration in the management of patients who fail to respond to chemotherapy or who relapse after radiation therapy. Of patients with metastatic seminoma who relapse after treatment, approximately 10% to 15% have NSGCT elements at the site of relapse. An autopsy study showed that 30% of patients who die of seminoma have NSGCT elements at metastatic sites (Bredael et al, 1982).

The risk of teratoma at metastatic sites has a substantial effect on treatment algorithms for NSGCT and necessitates the frequent use of postchemotherapy surgery (PCS) in patients with advanced disease. The risk of teratoma in the retroperitoneum in low-stage NSGCT has also influenced many clinicians to favor RPLND over chemotherapy in situations where the risk of occult distant metastases is low. As discussed earlier, teratoma is not sensitive to chemotherapy, and the outcome of patients with metastatic teratoma is related to the completeness of surgical resection.

Because GCTs are almost always cured, numerous clinical trials have been conducted in an attempt to minimize treatment and avoid unnecessary therapies in an effort to reduce short-term and particularly long-term side effects and toxicity. One approach has been to limit the number of patients who receive two interventions ("double therapy"): either surgery or chemotherapy and not both. However, because NSGCTs are usually mixed tumors, and teratoma often exists at metastatic sites with other GCT elements, **"cure" often requires chemotherapy to kill the chemosensitive components and surgery to remove teratomatous components.** It is widely accepted that the successful integration of systemic therapy and PCS is a major contributing factor to the improved cure rates for metastatic GCT seen over the past several decades. Although minimizing unnecessary treatment is an important goal, chemotherapy, radiation therapy, and CT imaging are associated with an increased lifetime risk of secondary malignant neoplasms (SMN) and/or cardiovascular disease (Meinardi et al, 2000; Zagars et al, 2004; Brenner and Hall, 2007; van den Belt-Dusebout et al, 2007; Tarin et al, 2009). In contrast, RPLND when performed by experienced surgeons is associated with a substantially more favorable long-term toxicity profile.

KEY POINTS: CONTRASTING SEMINOMA AND NONSEMINOMA GERM CELL TUMOR

- Compared with NSGCT, seminoma is associated with an indolent natural history with a lower incidence of metastatic disease and lower rates of occult retroperitoneal and distant metastases in patients with CS I, IIA, and IIB.
- No poor-risk prognostic category exists for metastatic seminoma, and substantially more patients are classified as good risk by IGCCCG criteria compared with NSGCT.
- Seminoma is associated with increased sensitivity to radiation therapy and platin-based chemotherapy compared with NSGCT.
- Serum hCG is elevated in only 15% of patients with metastatic seminoma, and serum tumor marker levels are not used to guide treatment decisions.
- Teratoma at metastatic sites is less of a concern for seminoma compared with NSGCT but should be considered in patients who fail to respond to conventional therapy.

Intratubular Germ Cell Neoplasia

ITGCN is diagnosed by testicular biopsy performed for the investigation of infertility, contralateral testis biopsy in patients with GCT, or within the affected testis in a patient undergoing testis-sparing surgery. The rationale for treatment of ITGCN is based on the high risk of developing invasive GCT (Skakkebaek et al, 1982; Dieckmann and Skakkebaek, 1999). Treatment options include orchiectomy, low-dose radiotherapy, and close observation. The choice of therapy should be individualized based on the patient's desire for future paternity, the presence or absence of a normal contralateral testis, and the patient's desire to avoid testosterone replacement therapy. Radical orchiectomy is the most definitive treatment, although low-dose radiotherapy (≥ 20 Gy) is associated with similar rates of local control with the prospect of preserving testicular endocrine function owing to the relative radioresistance of Leydig cells compared with germinal epithelium (Heidenreich et al, 2001; Montironi, 2002; Dieckmann et al, 2003). However, testosterone replacement therapy is ultimately required in up to 40% of patients, and patients should be monitored after radiotherapy for adequate testicular androgen production (Heidenreich et al, 2001; Petersen et al, 2002). To preserve testicular endocrine function, dose reductions to less than 20 Gy have been investigated, but cases of recurrent ITGCN have been observed (Classen et al, 2003a; Dieckmann et al, 2003). For patients with a normal contralateral testis who desire future paternity, radical orchiectomy is preferred because scatter to the contralateral testis from radiotherapy may impair spermatogenesis. For patients with abnormal semen parameters but sufficient for assisted reproductive techniques, close surveillance with periodic ultrasound evaluation of the testis is a reasonable strategy with deferred therapy until successful pregnancy and/or development of GCT. Another option for these patients is testis exploration, sperm harvesting, and cryopreservation for assisted reproductive techniques and radical orchiectomy followed by testosterone replacement therapy.

Patients with ITGCN who are scheduled to receive cisplatin-based chemotherapy represent a unique circumstance because chemotherapy may reduce (but not eliminate) the risk of GCT. A study estimated the risk of testicular GCT after chemotherapy in a patient with ITGCN to be 21% at 5 years and 45% at 10 years (Christensen et al, 1998). These patients may be treated by low-dose radiotherapy after completion of chemotherapy, or they may undergo testis biopsy 2 years or more after chemotherapy with therapy reserved for patients with evidence of ITGCN (Krege et al, 2008a, 2008b).

Nonseminoma Germ Cell Tumor

Clinical Stage I Nonseminoma Germ Cell Tumor. Approximately one third of patients with NSGCT have CS I with normal

KEY POINTS: INTRATUBULAR GERM CELL NEOPLASIA

- ITGCN is a precursor lesion for GCT and is associated with a 50% risk of developing an invasive GCT within 5 years.
- Radical orchiectomy and low-dose (≥ 20 Gy) radiation therapy are effective treatment options for ITGCN.

serum tumor markers after orchiectomy. The optimal management of these patients continues to generate controversy because the long-term survival associated with surveillance, RPLND, and primary chemotherapy approaches 100%. Contributing to the controversy is the fact that occult metastases in the retroperitoneum or at distant sites are present in only 20% to 30% of patients overall. Any intervention after orchiectomy, with the potential for short-term and long-term morbidity, represents overtreatment for the 70% to 80% of patients with disease limited to the testis. Most centers employ a risk-adapted approach based on the probability of occult metastasis, although surveillance is the preferred approach at selected centers, regardless of a man's risk.

Risk Assessment. Numerous studies have attempted to identify histopathologic factors within the primary tumor that are predictive of the presence of occult metastasis. The most commonly identified risk factors for occult metastasis are LVI and a predominant component of EC. The definition of EC predominance in the literature varies from 45% to 90%. The reported rate of occult metastasis (based on observed relapses on surveillance or lymph node metastasis at RPLND) with LVI and EC predominance varies from 45% to 90% and 30% to 80%, respectively (Heidenreich et al, 1998; Sogani et al, 1998; Hermans et al, 2000; Sweeney et al, 2000; Alexandre et al, 2001; Roelleveld et al, 2001; Albers et al, 2003; Vergouwe et al, 2003; Nicolai et al, 2004; Stephenson et al, 2005a). In the absence of these two risk factors, the risk of occult metastasis is less than 20%. Other identified risk factors include advanced pT stage, absence of mature teratoma, absence of yolk sac tumor, presence of EC (regardless of the percent composition), percentage of MIB-1 staining, tumor size, and patient age. In a pooled analysis of 23 studies assessing predictors of occult metastasis in CS I NSGCT, Vergouwe and associates (2003) identified LVI (odds ratio 5.2), MIB-1 staining greater than 70% (odds ratio 4.7) and EC predominance (odds ratio 2.8) as the strongest predictors, and these factors were present in 36%, 55%, and 51% of patients.

As discussed previously, the results of abdominopelvic CT imaging should be considered when formulating treatment recommendations because a size cutoff of 1 cm is associated with a high false-negative rate. Retroperitoneal lymph nodes greater than 5 to 9 mm in the primary landing zone should be viewed with suspicion for regional lymph node metastasis.

Numerous risk groups and prognostic indices have been proposed based on the presence or absence of several of these risk factors, most commonly on the basis of LVI and EC predominance (Freedman et al, 1987; Read et al, 1992; Heidenreich et al, 1998; Sogani et al, 1998; Hermans et al, 2000; Alexandre et al, 2001; Albers et al, 2003; Nicolai et al, 2004; Stephenson et al, 2005a). Classification of patients as low versus high risk based on LVI and EC predominance applies to the risk of occult metastatic disease in patients with CS I and should not be confused with the IGCCCG risk classification for metastatic NSGCT (discussed previously). Only one of these prognostic models has been prospectively validated, and none have considered the results of staging CT imaging (Freedman et al, 1987; Read et al, 1992). Three prospective studies suggest that LVI and EC predominance may be associated with a risk of metastasis between 35% and 55%, not between 50% and 70% as has been reported in most older studies. A surveillance series from Princess Margaret Hospital reported a relapse rate of 52% among patients with LVI and/or pure EC (Sturgeon et al, 2011). Similarly, a series from British Columbia and Portland, Oregon, reported that LVI was associated with a relapse rate of 50%, whereas EC predominance was associated with a relapse rate of 33% (Kollmannsberger et al, 2010b). Likewise, a population-based

surveillance study from Scandinavia reported a 42% relapse rate in patients with LVI (Tandstad et al, 2009). Lastly, only 18% of patients with CS I NSGCT treated by RPLND in a randomized trial had retroperitoneal lymph node metastasis despite the fact that 42% had evidence of LVI in the primary tumor (Albers et al, 2008). This lower than expected rate of occult metastasis may be due to greater scrutiny of staging CT imaging for abnormal lymph nodes and/or stage migration.

Surveillance. The rationale for surveillance is based on the fact that 70% to 80% of patients with CS I NSGCT are cured by orchiectomy alone and the ability to salvage virtually all relapsing patients with chemotherapy based on the long-term cure rates achieved for chemotherapy for good-risk metastatic NSGCT (International Germ Cell Consensus Classification, 1997). Surveillance offers the potential of reducing treatment-related toxicity by restricting treatment to patients with a proven need for it. Surveillance series have reported overall and disease-specific survival rates indistinguishable from rates seen with RPLND and primary chemotherapy. As a result, initial surveillance is regarded as a standard treatment option for CS I NSGCT. The disadvantages of surveillance are that it is associated with the highest risk of relapse, the need for long-term (>5 years) surveillance, the potential for SMN owing to intensive surveillance CT imaging (Brenner and Hall, 2007; Tarin et al, 2009), and the more intensive therapy required to treat patients at the time of relapse than if they had received treatment at diagnosis.

Published surveillance series have reported results on more than 3000 men, with a mean relapse risk of 28% and 1.2% cancer-specific mortality. The 11 largest series are summarized in Table 34-3 (Freedman et al, 1987; Read et al, 1992; Gels et al, 1995; Sogani et al, 1998; Colls et al, 1999; Sharir et al, 1999; Francis et al, 2000; Daugaard et al, 2003; Ernst et al, 2005; Tandstad et al, 2009; Kollmannsberger et al, 2010b; Tandstad et al, 2010; Sturgeon et al, 2011). More than 90% of relapses occur within the first 2 years, but late relapses (>5 years) are seen in 1% of patients (5% in some reports) (Daugaard et al, 2003; Sturgeon et al, 2011). In more contemporary series, 65% to 75% of relapses are contained in the retroperitoneum, with or without elevated serum tumor markers (Tandstad et al, 2009; Sturgeon et al, 2011). Induction chemotherapy is the most common treatment used for patients with relapses because most have bulky (>3 cm) retroperitoneal lymphadenopathy, elevated serum tumor markers, or distant metastasis. However, patients with normal serum tumor markers and relapses limited to nonbulky (<3 cm)

retroperitoneal lymphadenopathy may be managed initially with RPLND (Stephenson et al, 2007).

The surveillance schedule employed in published series is highly variable, and no schedule has been demonstrated to be superior to another in terms of survival. Given that most relapses occur within the first 2 years, surveillance imaging and testing is intense in years 0 to 2, with less frequent testing in years 3 to 5. The risk of late relapse mandates surveillance beyond 5 years, but whether such surveillance should include CT scans is controversial. The frequency of abdominopelvic CT imaging varies across multiple series from 2 to 13 or more scans within the first 5 years of follow-up. A randomized trial of two versus five CT scans in years 1 to 2 reported no significant differences in survival, IGCCCG risk category at relapse, or CS at relapse (Rustin et al, 2007). Noncompliance with the prescribed surveillance schedule has been reported in 35% to 80% of patients in published series (Howard et al, 1995; Hao et al, 1998; Ernst et al, 2005).

Retroperitoneal Lymph Node Dissection. The rationale for RPLND for CS I NSGCT is based on the following factors: (1) retroperitoneum is the most common site of occult metastatic disease, with low risk of associated systemic disease; (2) 15% to 25% incidence of retroperitoneal teratoma (which is resistant to chemotherapy) in patients with occult metastasis; (3) low risk of abdominopelvic recurrence after full, bilateral template RPLND, obviating the need for routine surveillance CT imaging; (4) high cure rates after RPLND alone for patients with low-volume (pN1) retroperitoneal malignancy and teratoma (pN1-3); (5) avoidance of chemotherapy in greater than 75% or more of patients if adjuvant chemotherapy is restricted to patients with extensive retroperitoneal malignancy (pN2-3); (6) high salvage rate of relapses with good risk and induction chemotherapy; and (7) low short-term and long-term morbidity when nerve-sparing RPLND is performed by experienced surgeons. In low-stage NSGCT, the therapeutic focus is the retroperitoneum, for which RPLND provides the most effective control with the lowest rates of serious long-term morbidity. The disadvantages of RPLND are that all patients undergo major abdominal surgery, it requires the availability of experienced surgeons and may not be deliverable to all patients, and it is associated with the highest rate of double therapy.

The seven largest RPLND series for CS I NSGCT are summarized in Table 34-4 (Richie, 1990; Donohue et al, 1993; Hermans et al, 2000; Nicolai et al, 2004; Stephenson et al, 2005b; Albers et al, 2008; Williams et al, 2009b). The rate of pathologic stage II in these series ranges from 19% to 28%, and an estimated 66% to 81% of

GCT, germ cell tumor; NR, not reported; PS, pathologic stage.

these patients were cured after RPLND alone (Donohue et al, 1993; Hermans et al, 2000; Sweeney et al, 2000; Rabbani et al, 2001; Nicolai et al, 2004; Stephenson et al, 2005a, 2005b). The long-term cancer-specific survival with RPLND (with or without adjuvant chemotherapy) approaches 100%, and the risk of late relapse is negligible. Most RPLND series have reported retroperitoneal recurrences in less than 2% of patients, demonstrating its efficacy for control of disease of the retroperitoneum (Donohue et al, 1993; Hermans et al, 2000; Stephenson et al, 2005b).

A full, bilateral template dissection is associated with the lowest risk of abdominopelvic recurrence (<2%) and the highest rate of antegrade ejaculation (>90%) when nerve-sparing techniques are employed (Jewett, 1990; Donohue and Foster, 1998; Stephenson et al, 2005b; Eggener et al, 2007b; Subramanian et al, 2010). For this reason, it is now considered by many to be the standard of care for primary RPLND (Stephenson et al, 2011). A randomized trial of primary RPLND (plus adjuvant bleomycin-etoposide-cisplatin [BEP]×2 for pathologic stage II) versus BEP×1 chemotherapy for CS I NSGCT showed a significant improvement in 2-year progression-free survival with chemotherapy (99% vs. 92%), although no GCT deaths were observed in either arm (Albers et al, 2008). The local recurrence rate was 11% in patients with histologically negative retroperitoneal lymph nodes at RPLND, which was substantially higher than the local recurrence rate among all patients from experienced centers. The patients in this trial were treated at 61 different centers in Germany. The relative inexperience of surgeons and unilateral templates likely contributed to these poor results. Patients who opt for RPLND should have this procedure performed by an experienced surgeon with a full, bilateral template dissection. Otherwise, patients should go on surveillance or receive primary chemotherapy.

RPLND is a curative procedure in 60% to 90% of patients with pN1 disease and up to 100% of patients with teratoma only (regardless of the extent of lymph node involvement) (Pizzocaro and Monfardini, 1984; Williams et al, 1987; Richie and Kantoff, 1991; Rabbani et al, 2001; Sheinfeld et al, 2003; Stephenson et al, 2005b). The risk of relapse in patients with pN2-3 disease is greater than 50% (Vogelzang et al, 1983; Williams et al, 1987; Socinski et al, 1988; Stephenson et al, 2005b). With two cycles of adjuvant chemotherapy (most commonly BEP×2 or etoposide-cisplatin [EP]×2), relapses are reduced to 1% or less (Behnia et al, 2000; Albers et al, 2003; Kondagunta et al, 2004). A randomized trial of adjuvant chemotherapy versus observation after RPLND for pathologic stage II showed a significant reduction in the risk of relapse (6% vs. 49%) but no difference in overall survival (Williams et al, 1987). Adjuvant chemotherapy and observation are acceptable treatment options for patients with pathologic stage II disease, and patients should be informed of the risk of relapse after RPLND and the potential benefits and risks of these approaches.

Primary Chemotherapy. In contradistinction to adjuvant chemotherapy given for pathologic stage II disease after RPLND, primary

chemotherapy refers to treatment administered to men with CS I NSGCT after orchiectomy. The goal of primary chemotherapy is to minimize the risk of relapse and to allow men to avoid RPLND and induction chemotherapy (for patients who relapse on surveillance). The rationale for primary chemotherapy is based on the efficacy of two cycles of chemotherapy to eradicate micrometastatic disease when given as adjuvant therapy after RPLND and the 20% to 25% need for chemotherapy despite RPLND (either as adjuvant therapy or for treatment of relapse) (Donohue et al, 1993; Hermans et al, 2000; Nicolai et al, 2004; Stephenson et al, 2005a). Primary chemotherapy offers patients the greatest chance of being relapse-free with any single treatment modality, and it can be delivered at community-based institutions (Tandstad et al, 2009, 2010). The disadvantages of primary chemotherapy are as follows: (1) it does not treat retroperitoneal teratoma and exposes patients to the potential for chemoresistant and/or late relapse (discussed later), (2) long-term surveillance CT imaging of the retroperitoneum is required, and (3) all patients are exposed to chemotherapy and the potential risk of late toxicity (e.g., cardiovascular disease and secondary malignancies). The risk of late toxicity from two cycles of chemotherapy is poorly defined, although there appears to be no safe lower limit.

Primary chemotherapy has been investigated in 12 published series, most of which have used BEP×2 (Table 34-5) (Abratt et al, 1994; Cullen et al, 1996; Pont et al, 1996; Ondrus et al, 1998; Bohlen et al, 1999; Amato et al, 2004; Chevreau et al, 2004; Oliver et al, 2004; Dearnaley et al, 2005; Albers et al, 2008; Tandstad et al, 2009, 2010). In men with LVI and/or EC predominance, it is possible to reduce the recurrence rate from 30% to 60% to about 2% to 3%. In 8 of the 12 series, no deaths from GCT were reported over an average median follow-up of 5 years. In the other four studies comprising 406 patients, 13 relapses (3%) were observed, and 6 (46%) of these relapsing patients died of GCT. Although primary chemotherapy is associated with the lowest risk of relapse, these relapses are less amenable to salvage therapy because they are chemoresistant, particularly if they have received a regimen other than standard dose BEP. In contrast, patients who relapse after RPLND or on surveillance are chemotherapy-naïve and are cured with chemotherapy in virtually all cases. Although relapses are uncommon with primary chemotherapy, virtually all occur in the retroperitoneum; this mandates the use of surveillance abdominopelvis CT imaging in the follow-up of these patients. Many European institutions prefer BEP×2 to RPLND because the latter is primarily used as a staging procedure, performed without curative intent (Krege et al, 2008a, 2008b; Schmoll et al, 2009b).

A randomized trial and a population-based study investigated the use of BEP×1 as primary chemotherapy for CS I NSGCT (Albers et al, 2008; Tandstad et al, 2009). Over a median follow-up of less than 5 years in both studies, the risk of relapse after BEP×1 ranged from 1% to 3%, and cancer-specific survival approached 100% in

*Chemotherapy regimens: BEP, bleomycin-etoposide-cisplatin; BOP, bleomycin-vincristine-cisplatin; CEB, carboplatin-etoposide-bleomycin; PVB, cisplatin-vinblastine-bleomycin.

†E: 360 refers to an etoposide dose of 360 mg/m²/cycle; E: 500 refers to an etoposide dose of 500 mg/m²/cycle.

GCT, germ cell tumor; NR, not reported; pts, patients.

both studies. BEP×1 needs to be compared with BEP×2 in a randomized trial to verify its safety and efficacy.

Treatment Selection for Clinical Stage I Nonseminoma Germ Cell Tumor. There are no randomized trials that compare the standard treatment approaches for CS I NSGCT. A phase III, randomized trial compared BEP×1 versus unilateral, modified-template RPLND (with BEP×2 for patients with pathologic stage II disease) (Albers et al, 2008). Although a statistically significantly reduced risk of relapse was reported with BEP×1 (hazard ratio [HR] 0.13, 95% confidence interval 0.02 to 0.55), no cancer-specific deaths were reported in either arm. This trial has been criticized because it compared two nonstandard treatment approaches for CS I NSGCT (Sheinfeld and Motzer, 2008).

Given the excellent long-term survival with surveillance, RPLND, and primary chemotherapy, it is inappropriate to recommend any specific treatment option because there are relative advantages and disadvantages of each approach in terms of treatment-related toxicity, the need for subsequent treatment, and intensity of surveillance testing and imaging. Likewise, patient preferences may vary and should be considered. Several clinical practice guidelines for CS I NSGCT have been published, and surveillance is generally recommended to low-risk patients, and surveillance, RPLND, or primary chemotherapy is recommended to high-risk patients (Albers et al, 2005; Motzer et al, 2006; Hotte et al, 2008; Krege et al, 2008a, 2008b; Schmoll et al, 2009b; Stephenson et al, 2011). Nguyen and colleagues (2010) developed a decision-analysis model that considered cancer outcomes, treatment-related toxicity, and patient preferences for important post-treatment outcomes to define the optimal treatment for CS I NSGCT. Surveillance is associated with the highest quality-adjusted survival when the estimated risk of relapse is less than 33% to 37%, and active treatment (RPLND or primary chemotherapy) is favored when the risk of relapse is greater than 46% to 54%.

Clinical Stage IS Nonseminoma Germ Cell Tumor. CS IS is defined as the presence of elevated serum tumor markers after orchiectomy without clinical or radiographic evidence of metastatic disease. Studies of primary RPLND for CS IS NSGCT reported that 37% to 100% of patients subsequently required chemotherapy for retroperitoneal metastasis, persistently elevated serum tumor

markers, or relapse (Davis et al, 1994; Saxman et al, 1996). There is consensus that these patients should be treated similarly to patients with CS IIC and III and receive induction chemotherapy. The cancer-specific survival after chemotherapy for CS IS is greater than 90% (Culine et al, 1996; International Germ Cell Consensus Classification, 1997). Slightly elevated and stable serum tumor marker levels after orchiectomy in patients without clinical evidence of disease should be interpreted cautiously because they may represent false-positive findings for disseminated NSGCT.

Clinical Stage IIA and IIB Nonseminoma Germ Cell Tumor. The optimal management of CS IIA and IIB NSGCT is controversial. RPLND (with or without adjuvant chemotherapy) and induction chemotherapy (with or without postchemotherapy RPLND) are accepted treatment options with survival rates exceeding 95%. No randomized trials have compared these treatment approaches. In a prospective, multicenter, nonrandomized trial of RPLND and two cycles of adjuvant chemotherapy versus induction chemotherapy, no significant differences in recurrence (7% for RPLND vs. 11% for chemotherapy) or overall survival were observed (Weissbach et al, 2000). A single-institution, nonrandomized, retrospective comparison of RPLND (and two cycles of adjuvant chemotherapy for pathologic stage II) and induction chemotherapy reported a significant reduction in the risk of recurrence with induction chemotherapy (98% vs. 79%), but cancer-specific survival approached 100% with both modalities (100% vs. 98%), patients undergoing RPLND received fewer cycles of chemotherapy (mean 4.2 vs. 1.4), and 51% of patients undergoing RPLND avoided chemotherapy (Stephenson et al, 2007).

The arguments in favor of RPLND for CS IIA and IIB are as follows: (1) 13% to 35% of patients have pathologically negative lymph nodes and avoid chemotherapy (Pizzocaro, 1987; Donohue et al, 1995; Weissbach et al, 2000; Stephenson et al, 2007); (2) approximately 30% have retroperitoneal teratoma, which is resistant to chemotherapy (Foster et al, 1996; Stephenson et al, 2007); (3) long-term cancer-specific survival is 98% to 100% with RPLND with or without adjuvant chemotherapy (Pizzocaro, 1987; Donohue et al, 1995; Weissbach et al, 2000; Stephenson et al, 2007); (4) 10% to 52% avoid any chemotherapy (Pizzocaro, 1987; Donohue et al, 1995; Weissbach et al, 2000; Stephenson et al, 2007); and (5)

ejaculatory function is preserved in 70% to 90% of patients (Richie and Kantoff, 1991; Donohue et al, 1995; Weissbach et al, 2000). The disadvantages of RPLND are as follows: (1) additional therapy is required in 48% or more of patients, (2) 13% to 15% have persistence of disease after RPLND and require a full induction chemotherapy regimen, and (3) high-quality RPLND may not be deliverable at all institutions (Weissbach et al, 2000; Stephenson et al, 2007).

The arguments in favor of induction chemotherapy are the following: (1) a complete response is achieved and PCS is avoided in 60% to 78% of patients, (2) treatment can be delivered at community-based institutions, and (3) cancer-specific survival is 96% to 100% (Peckham and Hendry, 1985; Logothetis et al, 1987; Socinski et al, 1988; Ondrus et al, 1992; Horwich et al, 1994; Lerner et al, 1995; Culine et al, 1997; Debono et al, 1997; Weissbach et al, 2000; Stephenson et al, 2007). The disadvantages of chemotherapy are the following: (1) all patients are exposed to the risk of long-term toxicity of chemotherapy, and (2) patients who do not undergo postchemotherapy RPLND are at risk of relapse with chemorefractory GCT.

Given that 13% to 35% of patients with CS IIA NSGCT have pathologically negative lymph nodes (a false-positive CT result), patients with indeterminate lesions on staging abdominopelvic CT imaging who are at otherwise low risk for metastatic disease may be observed closely initially to clarify subsequent treatment decisions. Treatment considerations for CS IIA and IIB NSGCT include the risk of occult systemic disease, risk of retroperitoneal teratoma, short-term and long-term treatment-related morbidity, and need for double therapy. The last consideration is of least importance but has strongly influenced opinion regarding the optimal treatment of these patients. As discussed earlier, because metastatic NSGCT frequently exists as chemosensitive malignant GCT and chemoresistant teratoma, "cure" often requires the combination of chemotherapy and surgery.

Experience with primary RPLND in low-stage NSGCT over the last two decades has identified parameters associated with systemic relapse. As with CS IS NSGCT, the presence of elevated AFP and hCG levels after orchiectomy is associated with an increased risk of systemic relapse after RPLND. Rabbani and colleagues (2001) reported relapses after RPLND in 4 of 5 patients (80%) with elevated postorchiectomy AFP or hCG levels compared with 7 of 45 patients (16%) with normal serum tumor markers. Stephenson and associates (2005b) identified the presence of elevated serum tumor markers (HR = 5.6, $P < .001$) and retroperitoneal lymphadenopathy greater than 3 cm (HR = 12.3, $P < .001$) as significant predictors of systemic relapse after RPLND. There is consensus that patients with CS IIA and IIB NSGCT and elevated AFP or hCG levels or bulky lymph nodes (>3 cm) should receive induction chemotherapy.

The presence of retroperitoneal teratoma is a limitation to any strategy for metastatic NSGCT that uses chemotherapy alone because it is resistant to chemotherapy. Overall, approximately 20% of patients with CS IIA and IIB have retroperitoneal teratoma, and this increases to 30% to 35% in patients with teratoma in the primary tumor (Donohue et al, 1995; Foster et al, 1996; Stephenson et al, 2005b). Residual microscopic teratoma may remain dormant and clinically silent throughout a patient's lifetime. It may also exhibit slow growth, which can be detected on surveillance CT imaging and is amenable to cure by surgical resection. However, growing teratoma syndrome, malignant transformation, and late relapse are the most serious (although rare) sequelae of unresected teratoma. RPLND is preferred as initial therapy in patients at risk for retroperitoneal teratoma who are at otherwise low risk for systemic disease (normal serum tumor markers, lymphadenopathy <3 cm).

Clinical Stage IIC and III Nonseminoma Germ Cell Tumor. Induction chemotherapy with cisplatin-based regimens is the initial approach used for the treatment of CS IIC and III NSGCT. As discussed previously, induction chemotherapy is also the preferred approach for CS IS and CS IIA and IIB with elevated AFP and hCG levels after orchiectomy. The specific regimen and

number of cycles are based on IGCCCG risk stratification (see Table 34-2) (International Germ Cell Consensus Classification, 1997).

The development of cisplatin-based chemotherapy represents the most important advancement in the treatment of GCT. Before the identification of cisplatin, complete responses to chemotherapy were achieved in 10% to 20% of patients, and the cure rate was only 5% to 10% (Einhorn, 1990). Long-term cure is now anticipated in 80% to 90% of patients with metastatic GCT. Randomized trials have evaluated the efficacy and safety of various drug combinations to determine the optimal regimen based on IGCCCG risk (Debono et al, 1997).

The initial landmark study was conducted at Indiana University using cisplatin-vinblastine-bleomycin (PVB)×4 in the 1970s and reported complete responses in 74% of patients and more than 70% long-term survivors (Beck et al, 2005). When it was demonstrated that etoposide could cure some patients with relapse after PVB chemotherapy, PVB×4 was compared with BEP×4 in a multicenter randomized trial. No significant difference in overall survival was seen between the two regimens (2-year survival 80%, $P = .11$), but BEP×4 was associated with less neuromuscular toxicity and was subsequently adopted as the standard regimen (Williams et al, 1987).

Chemotherapy for Good-Risk Nonseminoma Germ Cell Tumor

After BEP×4 became the standard regimen for advanced GCT, subsequent trials focused on reducing toxicity for patients with good-risk features and improving outcomes for patients with intermediate-risk and poor-risk disease. For good-risk patients, two randomized trials showed that BEP×3 is not inferior to BEP×4 (Einhorn et al, 1989; Saxman et al, 1998; de Wit et al, 2001). With 184 patients enrolled in the U.S. study, 92% of patients in each arm were continuously disease-free with a minimum follow-up of 1 year, and four deaths in each arm at 10 years were reported in a later analysis (Einhorn et al, 1989; Saxman et al, 1998). An international European trial comparing BEP×3 versus BEP×4 in more than 800 IGCCCG good-risk patients reported similar outcomes with respect to 2-year progression-free survival (90% vs. 89%) and overall survival (97% in each arm) (de Wit et al, 2001). As a result of these studies, BEP×3 became the standard regimen for good-risk GCT.

To reduce toxicity, investigators have studied the effect of omitting bleomycin and substituting carboplatin for cisplatin. All of the randomized trials in which a cisplatin regimen has been compared with a carboplatin regimen have reported superior outcomes with cisplatin (Bajorin et al, 1993; Bokemeyer et al, 1996b; Horwich et al, 1997, 2000; Bokemeyer et al, 2004). The issue of whether bleomycin can be safely omitted from cisplatin-based regimens in good-risk patients is much less clear and is one of the few remaining controversies in the management of advanced GCT. The rationale for omitting bleomycin is based on the risk of pulmonary complications (including pulmonary fibrosis) and Raynaud phenomenon. All of these studies have shown a trend toward superiority for the bleomycin-containing regimen, although no significant survival advantage has been shown in any of the trials (Bosl et al, 1988; Levi et al, 1993). EP×3 is inferior to BEP×3 (Loehrer et al, 1995). A European randomized trial comparing BEP×4 with EP×4 (with reduced doses of etoposide) reported a significantly higher complete response rate (95% vs. 87%, $P = .008$) with BEP×3 but no difference in overall survival (de Wit et al, 1997). More recently, a French randomized trial comparing BEP×3 with EP×4 (using conventional doses of etoposide) failed to show a statistically significant difference in the risk of relapse or survival between the two regimens (Culine et al, 2007). BEP×3 and EP×4 are both accepted regimens for patients with advanced GCT and good-risk features by IGCCCG criteria, and the 5-year overall survival is 91% to 94% (International Germ Cell Consensus Classification, 1997; van Dijk et al, 2006).

Chemotherapy for Intermediate-Risk and Poor-Risk Nonseminoma Germ Cell Tumor

BEP×4 has been the standard regimen for advanced GCT with intermediate-risk and poor-risk features since 1987, and the corresponding 5-year survival rate is 79% for intermediate-risk patients and 48% for poor-risk patients (*International Germ Cell Consensus Classification, 1997*). Ifosfamide-based regimens using either etoposide-ifosfamide-cisplatin (VIP×4) or vinblastine-ifosfamide-cisplatin (VeIP×4) have been investigated in randomized trials and compared with BEP×4 (*de Wit et al, 1998; Nichols et al, 1998; Hinton et al, 2003*). The multicenter U.S. trial reported results on nearly 300 men with advanced GCT, with 13%, 23%, and 64% classified as good, intermediate, and poor risk by IGCCCG criteria (*Nichols et al, 1998; Hinton et al, 2003*). Comparing BEP×4 with VIP×4, the 2-year survival was 71% versus 74%, and the 5-year survival was 57% versus 62%; neither 2-year survival nor 5-year survival was significantly different (*Nichols et al, 1998*). The European study closed prematurely when the results of the U.S. study became available. Nevertheless, with 84 patients enrolled and more than 7 years' median follow-up, there were two deaths in the BEP×4 arm and one death in the VIP×4 arm, and overall survival at 5 years was greater than 80% (*de Wit et al, 1998*). In both BEP×4 versus VIP×4 trials, there were more deaths with BEP×4, but the differences were not significant. Because VIP×4 resulted in more high-grade hematologic and urologic toxicity, BEP×4 has remained the standard regimen for intermediate-risk and poor-risk GCT. However, these trials showed that comparable cancer outcomes could be achieved when ifosfamide is substituted for bleomycin. VIP×4 may be substituted for BEP×4 in patients with compromised pulmonary function and in patients in whom extensive chest surgery is likely to be performed to remove residual disease after chemotherapy (*Kesler et al, 2008*).

High-dose chemotherapy (HDCT) using carboplatin-etoposide-based regimens with autologous stem cell support (also termed *stem-cell rescue*) has been investigated as an alternative to BEP×4 in patients with GCT with a poor prognosis. The rationale for HDCT is the hypothesis that increasing dosage may overcome chemotherapy resistance. The most widely studied regimens have included carboplatin-etoposide alone or in combination with cyclophosphamide, ifosfamide, paclitaxel, or thiotepa (*Beyer et al, 1996; Bokemeyer et al, 2002a; Einhorn et al, 2007; Kondagunta et al, 2007; Lorch et al, 2007; Kollmannsberger et al, 2009*). Carboplatin is used in HDCT regimens because of dose-limiting nephrotoxicity and neuropathy with cisplatin. A randomized trial in 219 patients with intermediate-risk (21%) and poor-risk (79%) GCT randomly assigned to BEP×4 versus BEP×2 followed by two cycles of high-dose carboplatin-etoposide-cyclophosphamide and autologous stem cell support showed no significant difference in the 1-year durable complete response rate (48% vs. 52%, $P = .5$) or overall survival (*Motzer et al, 2007*). For patients in both arms, the 2-year survival was 83%, and the 5-year survival was 71%. However, toxicity was more severe for patients receiving HDCT. A smaller randomized trial also failed to demonstrate improved survival with HDCT compared with standard-dose regimens as first-line therapy for patients with metastatic GCT with poor prognosis (*Droz et al, 2007*). As a result, BEP×4 remains the standard first-line regimen in patients with intermediate-risk and poor-risk disease.

Although the standard chemotherapy for men with poor-risk disease has not changed in more than 20 years, the outcome of these men appears to have improved over time. In the original IGCCCG analysis, the 5-year overall survival for poor-risk patients was 48%, whereas survival rates of 60% or greater have been reported in subsequent multicenter randomized trials (*Hinton et al, 2003; Droz et al, 2007; Motzer et al, 2007; Culine et al, 2008*). A meta-analysis of 10 studies enrolling 1775 patients with disseminated NSGCT (including 456 poor-risk patients) reported that the pooled 5-year survival estimate for poor-risk patients was 71% (*van Dijk et al, 2006*).

Management of Residual Masses in Nonseminoma Germ Cell Tumor after Chemotherapy

To assess the response to first-line, cisplatin-based chemotherapy, patients are restaged with serum tumor markers and imaging studies of the chest, abdomen, and pelvis (including other sites of disease if present before chemotherapy). Patients are classified into the following categories based on their response to chemotherapy: (1) complete response, defined by normalization of serum tumor markers and resolution of radiographic disease (usually defined as residual masses ≤ 1 cm); (2) normalization of serum tumor markers with persistent radiographic tumor (partial remission—marker negative); (3) partial remission—marker positive; and (4) disease progression. Approximately 5% to 15% of patients fall into categories 3 and 4 and are typically managed with second-line (also termed *salvage*) chemotherapy (*Einhorn et al, 1989; Mead et al, 1992; de Wit et al, 1997; Debono et al, 1997*). There is clear consensus that patients with residual masses larger than 1 cm should undergo PCS (*Albers et al, 2005; Motzer et al, 2006; Krege et al, 2008a, 2008b; Schmoll et al, 2009b*). The management of patients with complete serologic and radiographic response is controversial, with some guidelines advocating close observation and others recommending PCS if the mass size before chemotherapy is greater than 3 cm (*Albers et al, 2005; Motzer et al, 2006; Krege et al, 2008a, 2008b; Schmoll et al, 2009b*).

The role of PCS for residual masses in patients with metastatic NSGCT is well established, and its rationale is based on several factors. Multiple large series of patients undergoing PCS for residual masses after first-line chemotherapy have consistently reported evidence of persistent GCT elements in the resected specimens in 50% or more. On average, histology of resected specimens demonstrates necrosis, teratoma, and viable malignancy (with or without teratoma) in 40%, 45%, and 15% of cases (*Table 34-6*) (*Toner et al, 1990; Gerl et al, 1995; Steyerberg et al, 1995; de Wit et al, 1997; Debono et al, 1997; Hartmann et al, 1997b; Sonneveld et al, 1998; Stenning et al, 1998; Steyerberg et al, 1998; Hendry et al, 2002; Albers et al, 2004; Spiess et al, 2006b; Carver et al, 2007a*). The 5-year overall survival of patients with complete resection of viable malignancy (with or without further chemotherapy) ranges from 45% to 77% (*Toner et al, 1990; Fox et al, 1993; Gerl et al, 1995; Hartmann et al, 1997b; Donohue et al, 1998; Stenning et al, 1998; Fizazi et al, 2001; Spiess et al, 2006a; Carver et al, 2007a; Fizazi et al, 2008*). In contrast, if left unresected, residual viable malignancy is destined to relapse, and only 25% to 35% of patients achieve durable remissions to second-line chemotherapy.

As discussed earlier, teratoma is resistant to chemotherapy and is present at metastatic sites in 15% or more of patients with disseminated NSGCT. The presence of metastatic teratoma is a limitation to any strategy for NSGCT that employs chemotherapy alone and necessitates the integration of chemotherapy and PCS in most patients with metastatic GCT. Unresected teratoma has the potential to exhibit rapid growth (growing teratoma syndrome), undergo malignant transformation, or cause late relapse, all of which may have lethal consequences. The outcome of metastatic teratoma is related to the completeness of surgical resection, and long-term survival is reported in 75% to 90% of patients who undergo PCS for residual teratoma (*Toner et al, 1990; Hartmann et al, 1997b; Sonneveld et al, 1998; Stenning et al, 1998; Carver et al, 2007c*). Lastly, in-field retroperitoneal relapse occurs in less than 2% of patients after a full, bilateral template RPLND, largely eliminating the need for radiographic surveillance of the abdomen and pelvis (*Carver et al, 2007b*).

Approximately 6% to 8% of PCS specimens contain evidence of non-GCT malignancy arising from malignant transformation of teratoma (*Toner et al, 1990; Little et al, 1994; Carver et al, 2007c*). The most common histology is rhabdomyosarcoma, and the presence of i(12p) or abnormalities of chromosome 12 in most specimens confirm its origin from GCT (*Motzer et al, 1998*). As with teratoma, the outcome of patients with malignant transformation is related to the completeness of surgical resection

TABLE 34-6 Histology of Postchemotherapy Residual Masses

Stomper et al, 1991	14	≤20	36%	14%	50%

because they are generally resistant to GCT-specific chemotherapy regimens. With complete resection, approximately 50% to 66% of patients survive, whereas most patients with incomplete resection experience rapid progression and death from GCT (Little et al, 1994; Comiter et al, 1998; Motzer et al, 1998; Lutke Holzik et al, 2003; Carver et al, 2007c). Chemotherapy specific to the transformed histology (e.g., sarcoma-specific regimen) has been investigated in two small series in selected patients with measurable disease limited to one histology. Partial responses were observed in 11 of 24 patients, 6 of whom are alive (Donadio et al, 2003; El Mesbahi et al, 2007).

Patients with necrosis only in the PCS specimens have a favorable prognosis, with relapse rates of 10% or less reported in most series (Toner et al, 1990; Hartmann et al, 1997b; Stenning et al, 1998; Carver et al, 2007a). Investigators have sought to identify factors that are reliably predictive of a high probability of necrosis to obviate the need for PCS in all patients with residual masses. In an early study, Donohue and coworkers (1987) reported that 0 of 15 patients without teratoma in the primary tumor and who achieved a 90% or greater reduction in the size of the residual mass with chemotherapy had no evidence of viable malignancy or teratoma at PCS. In contrast, seven of nine patients (78%) with teratoma in the primary tumor experiencing a similar reduction in the size of the metastasis with chemotherapy had evidence of viable malignancy and/or teratoma. The absence of teratoma in the primary tumor, the percentage reduction in the retroperitoneal mass with chemotherapy, and the size of the residual mass have consistently been identified as predictors of necrosis in PCS specimens (Toner et al, 1990; Stomper et al, 1991; Fossa et al, 1992; Steyerberg et al, 1995, 1998; Albers et al, 2004). However, despite statistical modeling using these and other factors, a consistent false-negative rate for necrosis of 20% has been reported (Steyerberg et al, 1995, 1998; Vergouwe et al, 2001). The presence of

necrosis only in the retroperitoneum cannot be predicted with sufficient accuracy to obviate safely the need for PCS in patients with residual masses. An important concept is that the absence of teratoma in the primary tumor does not reliably exclude its presence in the retroperitoneum (Toner et al, 1990; Beck et al, 2002). Investigators have also studied the utility of FDG-PET in the prediction of the histology of residual masses after first-line chemotherapy. The utility of FDG-PET in the prediction of retroperitoneal histology for NSGCT is limited by the fact that teratoma is not FDG-avid. In a prospective study of 121 patients with residual masses after induction chemotherapy, the predictive accuracy of FDG-PET (56%) for viable malignancy or teratoma was no better than CT (55%) or postchemotherapy serum tumor markers (56%) (Oechsle et al, 2008). FDG-PET has no role in the assessment of patients with NSGCT and residual masses after chemotherapy.

Approximately 26% to 62% of patients experience a serologic and radiographic complete response to first-line chemotherapy (Einhorn et al, 1989; Dearnaley et al, 1991; Mead et al, 1992; Debono et al, 1997; Stenning et al, 1998; Ehrlich et al, 2010; Kollmannsberger et al, 2010a). The optimal management of these patients is controversial. Advocates of PCS for these patients argue that residual mass size (or percentage reduction with chemotherapy) cannot be used to exclude reliably the presence of residual disease within the retroperitoneum. Numerous studies have demonstrated that, on average, patients with residual masses 20 mm or smaller have a 30% and 6% incidence of teratoma and viable malignancy, respectively (Table 34-7) (Fossa et al, 1989b; Toner et al, 1990; Stomper et al, 1991; Fossa et al, 1992; Steyerberg et al, 1995; Beck et al, 2002; Oldenburg et al, 2003; Stephenson et al, 2007). In an analysis of 295 patients with GCT managed at Indiana University after induction chemotherapy, 77 (26%) experienced a complete serologic and radiographic response to chemotherapy; 92% were alive at 5 to 10 years with an observational strategy

(Debono et al, 1997). This result highlights the therapeutic benefit of PCS for patients with residual masses. However, patients with complete serologic and radiographic response after induction chemotherapy represent a small minority of the overall population, indicating that observation is a reasonable option for only a select group of patients. Two studies have confirmed the low risk of relapse (4% to 10%) and 97% to 100% cancer-specific survival in patients with residual masses less than 1 cm who were observed without PCS (Ehrlich et al, 2010; Kollmannsberger et al, 2010a). However, most of these patients were good risk by IGCCCG criteria and did not have teratoma in the primary tumor, highlighting their select nature.

Approximately one third of patients have residual masses at multiple anatomic sites (retroperitoneum, chest, and left supraclavicular fossa are the most common), and these patients should undergo resection of all sites of measurable residual disease (Toner et al, 1990; Gerl et al, 1994; Hartmann et al, 1997a; McGuire et al, 2003). Although some centers have described performing simultaneous RPLND, thoracotomy, or neck dissection, our practice is to perform infradiaphragmatic and supradiaphragmatic resections as separate procedures. **Discordant histology between anatomic sites is reported in 22% to 46% of cases (Toner et al, 1990).** In general, the histology of PCS specimens from nonretroperitoneal sites is more likely to show necrosis (60%) and less likely to show viable malignancy (10%) and teratoma (30%) (Toner et al, 1990; Gerl et al, 1994; Hartmann et al, 1997a; Steyerberg et al, 1997). In addition to the size of residual masses and the number of anatomic sites, the presence of necrosis in postchemotherapy RPLND specimens is highly predictive of necrosis at other sites (Steyerberg et al, 1997). Of patients undergoing PCS for residual masses at different sites, only 19 of 159 (12%) who had necrosis in the RPLND specimen had either viable malignancy or teratoma at other sites (Tiffany et al, 1986; Gerl et al, 1994; Brenner et al, 1996; Steyerberg et al, 1997; Tognoni et al, 1998; McGuire et al, 2003). RPLND should be performed before PCS at other sites because the probability of residual disease in the retroperitoneum is highest, and RPLND histology is a strong predictor of histology at other sites. Observation of small residual masses at other sites is a reasonable option if the histology of the RPLND specimen is necrosis.

As mentioned earlier, the 5-year survival for patients with viable malignancy in PCS specimens is 45% to 77%. The role of postoperative chemotherapy in this setting is controversial. Fox and colleagues (1993) reported that 14 of 27 patients (70%) undergoing PCS for viable malignancy were free of recurrence with adjuvant chemotherapy versus 0 of 7 patients who were observed. In an international pooled analysis of 238 patients with viable malignancy in PCS specimens, Fizazi and colleagues (2001) identified prechemotherapy IGCCCG intermediate-risk and poor-risk disease, incomplete resection, and greater than 10% viable malignancy in PCS specimens as important prognostic factors. Patients with zero, one, and two to three risk factors had a 5-year overall survival of 100%, 83%, and 51%. Overall, a significant improvement in 5-year relapse-free survival was observed with postoperative chemotherapy (73% vs. 64%, $P < .001$), but there was no difference in 5-year overall survival (74% vs. 70%, $P = .7$). In a subset analysis, patients with one risk factor had an improved 5-year survival with postoperative chemotherapy (88% vs. 56%, $P = .02$), but patients with zero (100% survival, with or without chemotherapy) and two to three risk factors (55% vs. 60%) did not. In a confirmatory study, this prognostic index was validated for relapse-free and overall survival, and no significant difference in these end points was observed among the patients who did and did not receive postoperative chemotherapy (Fizazi et al, 2008). **A complete resection of residual masses is the most critical determinant of outcome for patients with viable malignancy in PCS specimens after first-line chemotherapy.** Immediate postoperative chemotherapy and surveillance may be reasonable options depending on the completeness of resection, IGCCCG risk group, and percent of viable cells. There is no consensus on the appropriate chemotherapy regimen and the number of cycles that should be used in this setting.

The importance of PCS was highlighted in a randomized trial of BEP×3 versus EP×4 in 257 men with good-risk metastatic NSGCT (Culine et al, 2007). As part of this trial, PCS was not dictated by protocol, and only 52% underwent PCS, which frequently involved resection of residual mass only. Overall, 14 of 20 (70%) relapsing patients and 7 of 14 (50%) patients who died of GCT either did not undergo PCS or relapsed in the retroperitoneum after inadequate RPLND. **These results suggest a substantial proportion of deaths from GCT may be prevented by the appropriate integration of chemotherapy and surgery.**

Relapsing Nonseminoma Germ Cell Tumor

The treatment of relapsing NSGCTs depends on what treatment the patient previously received and, in certain cases, the location of the relapse. Patients who have never received chemotherapy have a much more favorable prognosis than patients who have already been treated with chemotherapy for disseminated disease.

Chemotherapy-Naive Nonseminoma Germ Cell Tumor Relapse.

Chemotherapy-naive relapses occur in men with CS I NSGCT managed with either surveillance or RPLND and in men with CS IIA and IIB NSGCT treated with RPLND alone. Serum tumor markers are elevated 60% to 75% of the time in patients with CS I NSGCT who relapse on surveillance (Read et al, 1992; Gels et al, 1995; Sharir et al, 1999; Alexandre et al, 2001). **In general, these patients are treated with induction chemotherapy, with the specific regimen and duration of therapy determined by IGCCCG risk, and cure rates exceed 95%.** Select CS I patients on surveillance who relapse in the retroperitoneum with nonbulky (<3 cm) tumor and normal serum tumor markers may be treated by induction chemotherapy or RPLND (particularly if teratoma was present in the primary tumor) (Stephenson et al, 2007). The rationale for RPLND is to avoid or minimize the toxicity of chemotherapy, and long-term cure rates approach 100% with RPLND with or without adjuvant chemotherapy (Stephenson et al, 2007). CS I, IIA, and IIB patients who relapse after RPLND usually have involvement in the lungs or mediastinum. Virtually all of these patients are cured with first-line chemotherapy. Most relapses during surveillance or after RPLND occur within the first 2 years (Freedman et al, 1987; McLeod et al, 1991; Read et al, 1992; Albers et al, 1995; Gels et al, 1995; Sogani et al, 1998; Colls et al, 1999; Sharir et al, 1999; Francis et al, 2000; Daugaard et al, 2003; Stephenson et al, 2005b; Albers et al, 2008; Williams et al, 2009b; Zuniga et al, 2009; Kollmannsberger et al, 2010a). For the rare patient relapsing more than 2 years after orchiectomy or RPLND with normal tumor markers, biopsy or surgical resection should be strongly considered because of the likelihood of teratoma (Michael et al, 2000; Oldenburg et al, 2006). **Although the time to relapse is an important determinant of outcome in relapsing patients who have received prior chemotherapy, chemotherapy-naive patients who relapse more than 2 years after initial treatment have a prognosis similar to patients who relapse earlier.**

Nonseminoma Germ Cell Tumor Relapse Early after Chemotherapy.

Men who relapse after previously receiving first-line chemotherapy are treated with second-line (salvage) chemotherapy. Most relapses occur within 2 years of completing initial treatment, and these are classified as early relapse (de Wit et al, 1998; Nichols et al, 1998; Michael et al, 2000; Culine et al, 2007; Motzer et al, 2007). Relapses occurring more than 2 years after completion of initial therapy are classified as late relapse and differ substantially in terms of prognosis and therapy (discussed later). Early relapsing patients who appear to have a particularly unfavorable prognosis are patients who fail to achieve a complete response to first-line therapy or who relapse within 6 months of achieving a complete response; these patients are frequently termed *incomplete responders* (Fossa et al, 1999c). In an international pooled analysis of 1984 patients from 38 centers with relapse after first-line chemotherapy who received second-line chemotherapy, median progression-free survival was 10 months, and overall survival was 41 months (Lorch et al, 2010). Incomplete response to induction chemotherapy (HR = 1.4 to 1.9), primary mediastinal NSGCT

(HR = 3.0), nonpulmonary visceral metastasis (HR = 1.3), and elevated AFP (HR = 1.3 to 2.0) and hCG (HR = 1.5) were associated with increased risk of progression with second-line chemotherapy.

As discussed earlier, etoposide and ifosfamide were demonstrated to have substantial activity in patients with relapse after first-line chemotherapy, and this led to investigation of VIP×4 as a second-line regimen for relapsed GCT after PVB×4 (Loehrer et al, 1986; Einhorn, 1990). VeIP×4 was also studied as a second-line regimen in men who had received prior etoposide from BEP regimens (Loehrer et al, 1998). Studies of VIP×4 and VeIP×4 reported long-term remission rates of 23% to 35% and overall survival rates of 32% to 53% (McCaffrey et al, 1997; Loehrer et al, 1998; Pico et al, 2005). Studies of paclitaxel in the early 1990s showed activity in relapsed GCT, which led to development of the paclitaxel, ifosfamide, and cisplatin (TIP) regimen, and relapse-free survival has been reported in 36% to 47% of patients (Kondagunta et al, 2005; Mardiak et al, 2005; Mead et al, 2005). TIP×4, VIP×4, and VeIP×4 have never been compared in a randomized trial, and all are considered standard second-line regimens.

HDCT has also been investigated as a second-line (and third-line) regimen in patients with GCT relapse, although its role as second-line therapy is controversial. Indiana University has amassed the largest, single-institution series comprising 184 consecutive patients with metastatic GCT that progressed after first-line (73%) or second-line (27%) chemotherapy; 94% of these patients received two or more courses of HDCT (Einhorn et al, 2007). Over a median follow-up of 4 years, 63% of patients were continuously disease-free, including 70% and 45% of patients who received HDCT as second-line and third-line therapy, respectively. An international matched-pair analysis comparing 74 patients treated at a single institution who received two to three cycles of VIP followed by one cycle of HDCT using carboplatin-etoposide-ifosfamide with 119 patients treated at multiple centers throughout Europe who received standard-dose, second-line chemotherapy using various regimens reported a 10% improvement in event-free and overall survival with HDCT (Beyer et al, 2002). HDCT was compared with standard-dose, second-line chemotherapy in a randomized controlled trial enrolling 280 patients from 43 institutions. Patients in the standard-dose arm received VIP×4 or VeIP×4, depending on whether they received prior etoposide during first-line therapy. Patients in the HDCT arm received VIP/VeIP×3 followed by one cycle of high-dose carboplatin-etoposide-cyclophosphamide (Pico et al, 2005). Over a median follow-up of 45 months, there were no significant differences in complete and partial response rates (56% in both arms) or 3-year event-free (35% vs. 42%, $P = .16$) and overall (53% in both arms) survival.

There are several potential explanations for the lack of benefit of HDCT in the randomized trial despite the favorable results reported in the two nonrandomized studies. First, the results from single-arm trials may be subject to selection bias from differences in case mix. In addition, the results achieved at high-volume institutions with unique experience with HDCT may not be reproducible at other institutions. Alternatively, the treatment strategy employed in the randomized trial may have been suboptimal in that three cycles of standard-dose chemotherapy and only one cycle of HDCT were given. The treatment philosophy at Indiana University is to take patients to HDCT as quickly as possible, limit the number of cycles of standard-dose chemotherapy so that patients are able to tolerate HDCT better, and to give two cycles of HDCT. In the randomized trial, only 73% of patients assigned HDCT were able to receive it, and deaths resulting from toxicity on the HDCT arm were twice as common as on the standard-dose arm (7% vs. 3%). In the Indiana University series, 94% of patients were able to receive two cycles of HDCT, and the treatment-related death rate was 2.7%. Although HDCT as second-line therapy can cure a significant number of patients, the failure to demonstrate an improvement in survival compared with standard-dose regimens in three randomized trials (two as first-line therapy and one as second-line therapy) suggests it should not be considered a standard approach. At the present time, HDCT

should be offered only at specialized centers with extensive experience.

Treatment options for high-risk patients with relapse (e.g., incomplete responders) include standard-dose, second-line chemotherapy or HDCT (if administered at a specialized, high-volume institution). Standard-dose, second-line chemotherapy is the preferred approach for patients who relapse more than 6 months after first-line chemotherapy. Special mention is made of patients with declining or normalized serum tumor markers during first-line chemotherapy with enlarging (usually cystic) masses. These patients are considered to have growing teratoma syndrome. In these rare cases, chemotherapy is temporarily interrupted, and patients are taken for surgical resection. With complete surgical resection, the long-term prognosis for these patients is favorable (Logothetis et al, 1982; Andre et al, 2000; Spiess et al, 2007).

For patients relapsing after second-line chemotherapy, subsequent options are HDCT (if not given previously) and regimens including various combinations of the following agents: gemcitabine, paclitaxel, oxaliplatin, and irinotecan (Pectasides et al, 2004; De Giorgi et al, 2006; Bokemeyer et al, 2008; Nicolai et al, 2009; Oechsle et al, 2011; Veenstra and Vaughn, 2011).

Management of Residual Masses after Salvage Chemotherapy. Patients with serologic complete response to second-line chemotherapy with residual masses should undergo surgical resection after salvage chemotherapy. Patients undergoing surgical resection after salvage chemotherapy differ from patients undergoing PCS of residual masses after first-line chemotherapy in several ways. A complete resection of residual masses is feasible in only 56% to 72% of patients (compared with ≥85% after first-line therapy) (Fox et al, 1993; Debono et al, 1997; Hartmann et al, 1997b; Stenning et al, 1998; Eggener et al, 2007a). The histology of post-salvage chemotherapy surgical specimens is characterized by higher rates of viable malignancy (53%) and lower rates of necrosis (26%) and teratoma (21%) compared with surgical specimens after first-line chemotherapy. The long-term survival of patients is also substantially poorer with 5-year survival rates of 44% to 61% in most series (Fox et al, 1993; Hartmann et al, 1997b; Donohue et al, 1998; Stenning et al, 1998). Patients with viable malignancy in post-salvage chemotherapy surgical specimens have a particularly poor prognosis, and their survival is not improved with the use of postoperative chemotherapy.

Desperation Surgery. Most patients with progressive disease despite first-line and second-line chemotherapy have a dismal prognosis. However, a highly select group of patients with rising serum tumor markers who are deemed to have resectable disease limited to a single site (usually the retroperitoneum) may be candidates for salvage surgery, commonly referred to as desperation surgery. Although published studies are limited to small, single-institution case series, 47% to 60% have normalization of serum tumor markers postoperatively, and long-term survival is reported in 33% to 57% of patients after desperation surgery with or without postoperative chemotherapy (Wood et al, 1992; Murphy et al, 1993; Eastham et al, 1994; Albers et al, 2000; Beck et al, 2005).

Nonseminoma Germ Cell Tumor Relapse Late after Chemotherapy. Late relapse after chemotherapy is defined as relapse occurring more than 2 years after treatment. Roughly 3% of patients with NSGCT experience a late relapse (Ronnen et al, 2005; Oldenburg et al, 2006). Because late relapse is rare, a biopsy should be performed to confirm the diagnosis, particularly when serum AFP and hCG are normal. Late relapses can be divided into three histopathologic categories: viable malignancy (54% to 88%, yolk sac tumor most common), teratoma (12% to 28%), and malignant transformation (10% to 20%, adenocarcinoma most common) (Baniel et al, 1995; Gerl et al, 1997; Michael et al, 2000; George et al, 2003; Sharp et al, 2008).

Risk factors for late relapse have not been definitively identified, but a history of prior relapse and the presence of teratoma in PCS specimens (potentially for incomplete resection) are associated with an increased risk (Gerl et al, 1997; Shahidi et al, 2002). Most men with a late relapse have only one site of disease.

Most late relapses occur in the retroperitoneum (50% to 72%), 17% occur in the lungs, 9% occur in the mediastinum, 7% occur in the neck, and 4% occur in the pelvis (Baniel et al, 1995; Gerl et al, 1997; George et al, 2003; Dieckmann et al, 2005; Oldenburg et al, 2006; Sharp et al, 2008). Failure to control the retroperitoneum in the initial treatment phase is a major risk factor for late relapse. Serum AFP and hCG levels are elevated in about 50% and 25% of late relapses, respectively (Oldenburg et al, 2006). Patients with elevated serum tumor markers as the only manifestation of late relapse should be monitored closely until there is measurable disease (George et al, 2003).

Until more recently, late relapse was associated with a worse prognosis than early relapses, although contemporary data suggest these patients may have a similar probability of cure. In general, late relapse is resistant to chemotherapy, and the outcome is related to the ability to render patients disease-free by complete surgical resection (Gerl et al, 1997; Shahidi et al, 2002; George et al, 2003; Dieckmann et al, 2005; Oldenburg et al, 2006; Sharp et al, 2008).

The importance of surgery is related to the fact that teratoma and malignant transformation are inherently chemoinensitive, and viable malignancy is usually present in the setting of prior chemotherapy (platin-resistant). Of 32 patients with late relapse at Indiana University who received chemotherapy, only 6 (19%) achieved a complete response. Of the 49 patients treated initially with surgery, 45 (92%) were rendered disease-free (22 [45%] by surgery alone), and 29 (59%) are in complete remission. Overall, 69 (85%) patients achieved a disease-free state, and 58% were disease-free over a median follow-up of 25 months (George et al, 2003). In the Memorial Sloan-Kettering experience, the 5-year cancer-specific survival was 60%, and patients who had a complete surgical resection at the time of late relapse (60%) had significantly improved survival compared with patients without complete resection (40%) (79% vs. 36%, $P < .001$) (Sharp et al, 2008). The presence of symptoms and multifocal disease at late relapse were associated with inferior survival. In a German study of 72 patients with NSGCT and late relapse, 35 (49%) were in complete remission at last follow-up, most of whom were treated with a combination of chemotherapy and surgery (Dieckmann et al, 2005). The most favorable chemotherapy results for late relapse are with the TIP regimen (Kondagunta et al, 2005). An aggressive surgical approach to resect all disease is appropriate either as the primary treatment or, in the setting of unresectable disease, after chemotherapy.

Seminoma

Clinical Stage I Seminoma. Approximately 80% of patients with seminoma are CS I, and this is the most common presentation of testis cancer. The management of these patients has undergone substantial changes over the past two decades, and surveillance, primary radiotherapy, and primary chemotherapy with single-agent carboplatin are now accepted treatment options. More recent efforts have focused on reducing the therapeutic burden. Platinum-based chemotherapy and infradiaphragmatic radiotherapy are associated with an increased risk of late cardiovascular toxicity and SMN (Zagars et al, 2004; Travis et al, 2005; van den Belt-Dusebout et al, 2007; Beard et al, 2013). Minimizing target volume and dose has been investigated to reduce the toxicity of radiotherapy. Carboplatin is associated with less neurotoxicity, ototoxicity, and nephrotoxicity compared with cisplatin, but the risks of cardiovascular disease and SMN are largely unknown. In many instances, the short-term efficacy and safety of these approaches have been validated by randomized trials. Long-term cancer control with each of these modalities approaches 100%.

Primary Radiotherapy. The mainstay of treatment for CS I seminoma for the past four decades had been primary radiotherapy to the retroperitoneum and ipsilateral pelvis, termed *dog-leg configuration*. Published series of radiotherapy for CS I are listed in Table 34-8 (Fossa et al, 1989a; Warde et al, 1995; Fossa et al, 1999b; Classen et al, 2004; Jones et al, 2005; Oliver et al, 2005; Warde et al, 2005; Tandstad et al, 2011). The optimal radiation dose has

KEY POINTS: NONSEMINOMA GERM CELL TUMOR

- The optimal management of CS I NSGCT is controversial. Surveillance, primary RPLND, and primary chemotherapy with BEP×2 are accepted treatment options with long-term survival rates approaching 100% for each.
- A risk-adapted approach based on the presence of LVI and EC predominance is recommended. Surveillance is recommended for patients without these risk factors, and active treatment (RPLND or BEP×2) is recommended for patients with LVI and/or EC predominance. A non-risk-adapted approach, which includes surveillance as the recommended approach for all patients, is employed at some centers.
- Surveillance is not recommended for patients who are anticipated to be poorly compliant with follow-up imaging and clinical evaluation. The standard treatment approach for patients who relapse on surveillance is induction chemotherapy based on IGCCCG risk. However, selected patients with normal serum tumor marker levels and nonbulky (<3 cm) retroperitoneal adenopathy may also be managed with RPLND.
- BEP×2 is the standard regimen used for patients with CS I NSGCT who choose to receive chemotherapy. There is insufficient evidence at the present time to support BEP×1 as an acceptable alternative.
- A full, bilateral template with nerve sparing is the recommended approach for primary RPLND. Attempts to preserve ejaculatory function should not compromise oncologic efficacy. RPLND should be performed only by surgeons experienced with the procedure.
- Adjuvant chemotherapy after primary RPLND for pathologic stage II disease is associated with a substantial reduction in the risk of relapse but no difference in long-term survival compared with a strategy comprising observation with induction chemotherapy at the time of relapse. Adjuvant chemotherapy is usually recommended for patients with extensive retroperitoneal metastasis (pN2-3) and patients anticipated to be noncompliant with postoperative cancer surveillance imaging and testing.
- Induction chemotherapy and primary RPLND are accepted treatment options for patients with CS IIA and IIB NSGCT, with long-term cure in 95% or more. Induction chemotherapy is favored in patients with a high risk of occult metastatic disease on the basis of elevated serum tumor markers after orchiectomy and/or bulky (>3 cm) retroperitoneal lymphadenopathy.
- The management of patients with CS IS, IIC, and III NSGCT is induction cisplatin-based chemotherapy. The specific regimen and number of cycles is dictated by IGCCCG risk criteria. Patients with good-risk disease should receive BEP×3 or EP×4, and patients with intermediate-risk and poor-risk disease should receive BEP×4. With risk-appropriate chemotherapy and PCS, the survival of patients with good-risk disease is 89% to 94%, with intermediate-risk disease is 75% to 83%, and with poor-risk disease is 41% to 71%.
- Resection of all residual masses after chemotherapy is based on the incidence of residual cancer (either viable malignancy or teratoma) in 50% or more of patients.
- The use of adjuvant chemotherapy is controversial in patients with viable malignancy in residual masses after first-line chemotherapy.

not been defined; most centers use 20 to 30 Gy over 10 to 15 daily fractions (Fossa et al, 1989a; Warde et al, 1995; Fossa et al, 1999b). Long-term cancer-specific survival approaches 100%, and progression-free probability between 95% and 97% is reported (Fossa et al, 1989a; Warde et al, 1995; Fossa et al, 1999b; Warde et al, 2005; Kollmannsberger et al, 2010; Tandstad et al, 2011). In-field recurrence after dog-leg radiotherapy is less than 1%,

GCT, germ cell tumor.

obviating the need for routine surveillance abdominopelvic CT imaging. Inguinal metastases are uncommon in patients without prior inguinal or scrotal surgery. **The most common sites of recurrence are the thorax and left supraclavicular fossa. Virtually all recurrences are cured with first-line chemotherapy.** Selected patients with isolated inguinal relapse may be salvaged with radiotherapy or surgical resection. **The surveillance of patients after dog-leg radiotherapy consists of regular clinical assessment, chest radiography, and serum tumor markers.**

Most patients experience some acute side effects with adjuvant radiotherapy, which typically include transient nausea, vomiting, and diarrhea, which are usually mild and self-limited. Acute grade II to IV hematologic toxicity occurs in 5% to 15% of patients (Fossa et al, 1999b). Moderate and severe late gastrointestinal toxicity (usually chronic dyspepsia or peptic ulcer disease) is reported in 5% and less than 2% of patients, respectively. The testicular germinal epithelium is exquisitely sensitive to ionizing radiation, and scatter dose to the contralateral testis may be significant despite protective shielding. After dog-leg radiotherapy, persistent oligospermia is reported in 8% (Fossa et al, 1999b). The issue of late cardiac toxicity and SMN is particularly germane for these patients given the long anticipated life expectancy. **The actuarial risk of developing SMN is estimated to be 18% at 25 years after radiotherapy for seminoma, and there is a 2.64% risk of dying of SMN at 15 years, representing an 89% increased risk of death from nontesticular cancer (Travis et al, 2005; Beard et al, 2013).** Secondary leukemia is linked with radiotherapy and chemotherapy, whereas an increased incidence of upper gastrointestinal tract, bladder, and possibly pancreas cancers is associated with radiotherapy.

To reduce the toxicity of radiotherapy, efforts to minimize the target volume and dose have been evaluated in randomized trials. The Medical Research Council (MRC) in the United Kingdom conducted a randomized trial of dog-leg versus para-aortic radiotherapy for CS I seminoma (Fossa et al, 1999b). The rationale for omitting radiotherapy to the ipsilateral pelvis is based on the low rate (1% to 3%) of pelvic lymph node involvement in patients without prior inguinal or scrotal surgery. Restricting radiotherapy to the para-aortic strip may reduce the risk of SMN and improve recovery of spermatogenesis. The 3-year relapse-free survival (96% vs. 97%) and overall survival (99% vs. 100%) in the para-aortic versus dog-leg

arms were similar, but patients receiving para-aortic radiotherapy had an improved short-term recovery of spermatogenesis (although no difference was seen at 3 years). However, the para-aortic arm experienced a significant increase in the rate of pelvic recurrence (2% vs. 0%, $P = .04$). The small but significant risk of pelvic recurrence necessitates the use of routine surveillance pelvic CT imaging with the associated increased cost and radiation exposure (Brenner and Hall, 2007).

The MRC and the European Organisation for the Research and Treatment of Cancer (EORTC) also conducted a randomized trial of 20 Gy versus 30 Gy para-aortic radiotherapy for CS I seminoma (Jones et al, 2005). The 5-year relapse-free survival (96% vs. 97%) and overall survival (99.6% vs. 100%) were similar, but patients receiving 20 Gy experienced less acute gastrointestinal toxicity, leukopenia, and lethargy (although results were similar at 12 weeks). Further follow-up is necessary to assess the durability of these results. **Surveillance.** Given the potential for late toxicity with dog-leg radiotherapy, the 80% to 85% cure rate after orchiectomy, and the greater than 90% cure rates achieved with platin-based chemotherapy for advanced seminoma, surveillance has been evaluated at several centers. **Compared with NSGCT, surveillance for CS I seminoma is complicated by the limited utility of serum tumor markers to detect relapse and the need for long-term surveillance CT imaging because 10% to 20% of relapses occur 4 years or more after diagnosis (Chung et al, 2002).**

The largest surveillance series for CS I seminoma are listed in Table 34-9 (Horwich et al, 1992; von der Maase et al, 1993; Warde et al, 1995; Aparicio et al, 2003; Daugaard et al, 2003; Aparicio et al, 2005; Choo et al, 2005; Warde et al, 2005; Kollmannsberger et al, 2010c; Tandstad et al, 2011). **The 5-year relapse-free survival ranges from 80% to 86%, and cancer-specific survival approaches 100%. Of patients, 84% to 100% relapse in the retroperitoneum, and 18% to 24% have bulky retroperitoneal disease and/or distant metastases at the time of recurrence (Horwich et al, 1992; von der Maase et al, 1993; Warde et al, 1995; Aparicio et al, 2003; Choo et al, 2005).** Dog-leg radiotherapy is employed for treatment of relapse in 73% to 88% of patients, and cure rates of 70% to 90% are reported. Virtually all patients who relapse outside the retroperitoneum are cured with first-line chemotherapy.

GCT, germ cell tumor.

To detect and treat recurrences at an early stage, patients on surveillance should be followed with clinical assessment, chest radiography, serum tumor markers, and abdominopelvic CT imaging. Surveillance schedules employ assessments every 2 to 4 months in years 1 to 3, every 6 months in years 4 to 7, and annually thereafter. The necessary frequency of CT imaging is poorly defined; centers obtain CT imaging every 4 to 6 months in years 1 to 3, every 6 months in years 4 to 7, and annually thereafter. A trial from the MRC suggested that the frequency of surveillance CT imaging in low-risk CS I NSGCT in years 0 to 2 may be safely reduced from five times to two times without affecting survival or burden of therapy (Rustin et al, 2007). It is unclear whether these findings can be safely applied to surveillance for seminoma. Long-term follow-up is mandatory given the higher incidence of relapse after 5 years compared with NSGCT (Chung et al, 2002).

To select patients for active treatment better, investigators have endeavored to identify prognostic factors for occult metastasis. In a pooled analysis of three large surveillance series from the 1980s, tumor size larger than 4 cm and rete testis invasion were significant predictors of relapse in multivariable analysis (Warde et al, 2002). In contrast to NSGCT, LVI has not been identified as a significant predictor of relapse for CS I seminoma. The 5-year

relapse rates for patients with zero, one, and two risk factors were 12%, 16%, and 32%. In this cohort, 21% of patients had both rete testis invasion and tumor size larger than 4 cm. Primary radiotherapy or carboplatin for all “high-risk” patients would still expose two thirds of patients with CS I seminoma (who are cured by orchiectomy) to unnecessary therapy. However, prospective validation of these risk factors is currently lacking.

Primary Chemotherapy with Single-Agent Carboplatin. Primary chemotherapy with one to two cycles of single-agent carboplatin has also been investigated as an alternative to primary radiotherapy with the potential for reduced late toxicity. The rationale for single-agent carboplatin is based on the 65% to 90% reported complete response rates observed among patients with advanced seminoma (Horwich et al, 2000) and its reduced toxicity compared with cisplatin. Oliver and colleagues (1994) first described the use of one to two cycles of carboplatin in 78 patients and reported only two relapses and no deaths. The published studies of carboplatin in CS I seminoma are listed in Table 34-10 (Dieckmann et al, 2000; Reiter et al, 2001; Steiner et al, 2002; Aparicio et al, 2003, 2005; Oliver et al, 2005; Kollmannsberger et al, 2010c; Aparicio et al, 2011; Tandstad et al, 2011). No deaths from seminoma have been observed, and 3- to 5-year relapse-free rates are 91% to 100%.

The MRC and EORTC conducted a randomized, phase III clinical trial of one cycle of carboplatin versus 20 to 30 Gy para-aortic radiotherapy in 1477 patients with CS I seminoma (Oliver et al, 2005, 2011). Over a median follow-up of 6.5 years, the 5-year relapse-free survival was similar (94.7% vs. 96%), and only one death was observed in the para-aortic radiotherapy arm. In this trial, patients receiving carboplatin experienced less lethargy and time away from work than patients receiving radiotherapy, and acute grade III to IV hematologic toxicity was observed in 4% of patients. Carboplatin was associated with a reduction in the rate of contralateral second-primary testis cancers (0.3% vs. 1.7%, $P = .03$).

A concern with one cycle of carboplatin is the potential for inadequate dosing leading to an increased risk of relapse. A higher relapse rate with one versus two cycles has been seen when comparing different studies, and a higher risk of relapse was reported among patients receiving an inadequate dose of carboplatin in the MRC/EORTC trial (Dieckmann et al, 2000; Oliver et al, 2008). The optimal dosing of carboplatin is calculated by the formula $7 \times (\text{glomerular filtration rate [mL/min]} + 25) \text{ mg}$ (Calvert and Egorin, 2002). Carboplatin dosing should not be based on estimated glomerular filtration rate. It is recommended to base one cycle of carboplatin dosing on the results of radioisotope renal scans or administer two cycles of therapy.

Given the low overall risk of relapse with CS I seminoma, the lack of prospectively validated markers to identify a high-risk population, and the potential for late toxicity with radiotherapy and carboplatin, many clinical practice guidelines now recommend surveillance as the preferred approach (Krege et al, 2008a, 2008b; Schmoll et al, 2009a). Surveillance enables 80% to 85% of patients to avoid treatment-related toxicity, and relapses are effectively salvaged with dog-leg radiotherapy in most cases. However, surveillance must be continued more than 5 years, and frequent CT imaging is required. For noncompliant patients or patients unwilling to accept surveillance, primary radiotherapy or primary chemotherapy with one to two cycles of carboplatin is recommended.

Clinical Stage IIA and IIB Seminoma. Approximately 15% to 20% of patients with seminoma have CS II disease; 70% of these patients have CS IIA and IIB. Dog-leg radiotherapy using 25 to 30 Gy (including a 5- to 10-Gy boost to involved areas) is employed at most centers. The higher radiation doses administered to CS IIA and IIB patients is generally well tolerated with acute grade III to IV gastrointestinal toxicity reported in 8% to 10% of patients (Classen et al, 2003b). Prophylactic radiation to the left supraclavicular fossa is no longer practiced because less than 3% of patients are likely to benefit (Zagars and Pollack, 2001; Chung et al, 2003). Long-term disease-free survival rates of 92% to 100% for CS IIA and 87% to 90% for CS IIB have been reported, with in-field recurrences reported in 0% to 2% and 0% to 7% of cases, respectively (Zagars and Pollack, 2001; Classen et al, 2003b; Chung et al, 2004b). Adding single-agent carboplatin to 30 Gy dog-leg radiotherapy reduced the relapse rate from 30% to 6% in one series, although further data are required to assess the utility of this approach (Patterson et al, 2001). Relapses are cured in virtually all cases with first-line chemotherapy, and disease-specific survival approaches 100%. Routine surveillance CT imaging is unnecessary after complete resolution of disease.

Induction chemotherapy using first-line regimens (BEP \times 3 or EP \times 4) is an accepted alternative to dog-leg radiotherapy. The Spanish Germ Cell Cancer Study Group reported on the use of BEP \times 3 or EP \times 4 in 72 patients with CS IIA and IIB seminoma (Garcia-del-Muro et al, 2008). Overall, 83% of patients achieved a serologic and radiographic complete response; only one patient (1.3%) had residual mass larger than 3 cm, and the two patients who underwent PCS for residual masses had necrosis only in the resected specimens. The 5-year relapse-free survival was 90%, and overall survival was 90% to 95%. The SWENOTECA group similarly reported that there were no relapses among 73 CS IIA and IIB patients treated with cisplatin-based chemotherapy, whereas there were three relapses (10%) among 29 patients treated with radiotherapy. Induction chemotherapy is preferentially given to

patients with bulky (>3 cm) and/or multiple retroperitoneal masses because the risk of relapse is lower than with dog-leg radiotherapy (Patterson et al, 2001; Chung et al, 2004b; Garcia-del-Muro et al, 2008).

Clinical Stage IIC and III Seminoma. As with NSGCT, patients with CS IIC and III seminoma are treated with induction chemotherapy, with the regimen and number of cycles determined by IGCCCG risk. Of patients with advanced seminoma, 90% are classified as good risk and should receive either BEP \times 3 or EP \times 4 chemotherapy. Complete radiographic responses are reported in 70% to 90% of patients, and the 5-year overall survival is 91% (Loehrer et al, 1987; Mencil et al, 1994; International Germ Cell Consensus Classification, 1997; Gholam et al, 2003). Only 10% of advanced seminomas have nonpulmonary visceral metastasis (classified as intermediate risk by IGCCCG criteria). With BEP \times 4 chemotherapy, the 5-year overall survival is 79% and progression-free survival is 75 (International Germ Cell Consensus Classification, 1997). Single-agent carboplatin in advanced seminoma is associated with inferior survival compared with cisplatin-based regimens (Bokemeyer et al, 2004).

Management of Residual Masses after Chemotherapy. After first-line chemotherapy, 58% to 80% of patients have radiologically detectable residual masses (Motzer et al, 1987; Puc et al, 1996; Duchesne et al, 1997; Fossa et al, 1997; Herr et al, 1997; Flechon et al, 2002; De Santis et al, 2004). Spontaneous resolution of these masses is reported in 50% to 60% of cases, and the median time to resolution is 13 to 18 months (Flechon et al, 2002; De Santis et al, 2004). The histology of residual masses is necrosis and viable malignancy in 90% and 10% of cases, respectively (Puc et al, 1996; Herr et al, 1997; Ravi et al, 1999; Flechon et al, 2002; De Santis et al, 2004). PCS for seminoma is technically difficult (and frequently not feasible) because of the desmoplastic reaction that occurs after chemotherapy with resultant increased perioperative morbidity (Mosharafa et al, 2003). Surgical complete resections in seminoma after chemotherapy are reported in only 58% to 74% of patients (compared with $\geq 85\%$ after first-line chemotherapy for NSGCT) (Puc et al, 1996; Herr et al, 1997; Ravi et al, 1999; Flechon et al, 2002; De Santis et al, 2004). Teratoma and malignant transformation are much less of a concern with advanced seminoma. The management of postchemotherapy residual masses differs substantially for seminoma compared with NSGCT.

Investigators have endeavored to identify factors associated with a high risk of viable malignancy to justify PCS. Postchemotherapy radiotherapy has no role in the management of residual masses (Duchesne et al, 1997). The size of residual masses is an important predictor of viable malignancy; 27% to 38% of discrete residual masses larger than 3 cm contain viable malignancy compared with 0% to 4% for masses smaller than 3 cm (Puc et al, 1996; Herr et al, 1997; Flechon et al, 2002; De Santis et al, 2004). FDG-PET has been found to be a useful adjunct to CT imaging to select patients for PCS (De Santis et al, 2004). The specificity and sensitivity of a positive FDG-PET scan for masses larger than 3 cm were 100% and 80%, respectively. Patients with discrete residual masses larger than 3 cm should be evaluated further with FDG-PET, and patients with positive PET scans should undergo PCS. PET-negative residual masses larger than 3 cm and masses less than 3 cm should be observed. Inflammation and residual nonviable malignancy may cause a false-positive PET result if patients are scanned too soon after completing chemotherapy. FDG-PET should be delayed until at least 4 weeks after completion of chemotherapy.

Relapsed Seminoma

Chemotherapy-Naive Seminoma Relapse. Chemotherapy-naive relapse occurs in men with CS I seminoma on surveillance and in men with CS I and IIB seminoma treated with primary radiotherapy. For the former patients, dog-leg radiotherapy is employed for treatment of relapse in 73% to 88% of patients, and cure rates of 70% to 90% are reported. Patients with bulky (>3 cm) retroperitoneal masses and systemic relapse should receive first-line chemotherapy, and salvage rates approach 100%.

First-line chemotherapy cures virtually all patients who relapse outside the retroperitoneum after primary radiotherapy. Patients who relapse after single-agent carboplatin are considered to have chemotherapy-naïve relapse and should receive first-line cisplatin-based chemotherapy.

Early Relapse of Seminoma after Chemotherapy. An estimated 15% to 20% of patients with advanced seminoma relapse after induction chemotherapy, including 10% who achieve an initial complete response (Loehrer et al, 1987; Mencil et al, 1994; International Germ Cell Consensus Classification, 1997). In general, patients with incomplete response to first-line chemotherapy or relapse after an initial major clinical response have a poor prognosis with long-term survival rates of 20% to 50% (Miller et al, 1997; Vuky et al, 2002; Gholam et al, 2003). The small number of patients with seminoma who require second-line chemotherapy has limited the evaluation of unique treatment strategies, and relapsing patients are treated on regimens that were largely developed for NSGCT relapse. In two small studies, the efficacy of Velpx4 as second-line chemotherapy was evaluated in 36 patients with relapsed seminoma. Overall, 30 patients (83%) achieved a complete response to chemotherapy (with or without PCS), and 21 (53%) were continuously free of recurrence over a median follow-up of 72 to 84 months (Miller et al, 1997; Vuky et al, 2002). Vuky and coworkers (2002) also evaluated HDCT in 12 patients with advanced seminoma and an incomplete response to first-line chemotherapy, and 6 patients (50%) achieving a complete response remained free of recurrence. An important consideration for patients with advanced seminoma who relapse after first-line chemotherapy is the potential for teratoma at the site of relapse. Patients with normal serum tumor markers should undergo biopsy before starting second-line chemotherapy.

Late Relapse of Seminoma after Chemotherapy. In most published series, pure seminoma accounts for less than 8% of late relapse events (Baniel et al, 1995; George et al, 2003; Ronnen et al, 2005; Sharp et al, 2008). However, Dieckmann and colleagues (2005) reported a series of 122 patients with late relapse, of whom 50 (41%) had pure seminoma at diagnosis. Only 6 (12%) of these patients had received prior first-line chemotherapy, and most had received single-agent carboplatin or radiation therapy at diagnosis. Long-term control of cancer was achieved in 88% of patients. Late relapse of seminoma may have a favorable prognosis, particularly in patients without prior exposure to cisplatin.

Brain Metastases

About 1% of men with disseminated GCT have brain metastases detected before initiating chemotherapy, and between 0.4% and 3% develop brain metastases after first-line chemotherapy (Raina et al, 1993; International Germ Cell Consensus Classification, 1997; Fossa et al, 1999a). Brain metastases are associated with choriocarcinoma and should be suspected in any patient with a very high serum hCG level (Fossa et al, 1999a; Kollmannsberger et al, 2000; Salvati et al, 2006; Gremmer et al, 2008; Nonomura et al, 2009). Choriocarcinomas are highly vascular and tend to hemorrhage during chemotherapy, and death rates of 4% to 10% secondary to intracranial hemorrhage have been reported (Kollmannsberger et al, 2000; Nonomura et al, 2009). This risk must be considered in management of these patients, and neurologic changes need to be evaluated expeditiously.

The 5-year overall survival in patients with brain metastases is 33% for patients with disseminated NSGCT and 57% for patients with seminoma (International Germ Cell Consensus Classification, 1997). Men who relapse in the brain after achieving a complete response to chemotherapy appear to have a worse prognosis than patients with brain involvement at diagnosis, with overall survival rates of 39% to 44% for isolated brain metastases and 2% to 26% for brain metastases associated with other sites of disease (Fossa et al, 1999a; Kollmannsberger et al, 2000; Hartmann et al, 2003; Salvati et al, 2006; Gremmer et al, 2008; Nonomura et al, 2009). Case studies and pooled analyses of patients with GCT and brain metastases have reported outcomes with various

KEY POINTS: SEMINOMA

- The optimal management of CS I seminoma is controversial. Surveillance, primary radiotherapy (20 to 30 Gy to the para-aortic region with or without ipsilateral pelvis), and primary chemotherapy with carboplatin (one to two cycles) are accepted treatment options with long-term survival rates approaching 100% for each.
- Prognostic factors for occult metastases in CS I seminoma are not as well developed as for NSGCT. Given the overall low risk of occult metastases (15% to 20%), the inability to identify a high-risk population on the basis of histopathologic factors in the primary tumor, and the potential for late toxicity with primary radiotherapy, surveillance has become the recommended treatment approach for CS I seminoma.
- Surveillance is not recommended to patients who are anticipated to be poorly compliant with follow-up imaging and clinical evaluation. The standard treatment approach to patients who relapse on surveillance is dog-leg radiotherapy (25 to 35 Gy), although patients with bulky retroperitoneal lymphadenopathy or distant metastases should receive IGCCCG risk-appropriate first-line chemotherapy.
- Primary radiotherapy and primary chemotherapy with single-agent carboplatin are associated with similar rates of cure and survival. Patients who receive para-aortic radiotherapy and patients who receive carboplatin require periodic CT imaging in the surveillance of recurrent disease after treatment; this is not required for patients who receive dog-leg radiotherapy.
- Dog-leg radiotherapy (25 to 35 Gy) and first-line chemotherapy (BEPx3 or EPx4) are accepted treatment options for patients with CS IIA and IIB seminoma and nonbulky (<3 cm) retroperitoneal lymph node metastasis. First-line chemotherapy (BEPx3 or EPx4) is recommended for bulky (>3 cm) and/or multifocal retroperitoneal metastases.
- The first-line treatment of patients with CS IIC and III seminoma is cisplatin-based chemotherapy, and the specific regimen and number of cycles are dictated by IGCCCG risk criteria. Patients with good-risk disease should receive BEPx3 or EPx4, and patients with intermediate-risk disease should receive BEPx4.
- Patients with discrete, residual masses larger than 3 cm after first-line chemotherapy should undergo further evaluation with FDG-PET imaging. Patients with PET-positive residual masses should undergo PCS. Residual masses that are PET-negative or less than 3 cm can be safely observed after chemotherapy.

treatment strategies, but there are no randomized trials to define optimal management clearly (Spears et al, 1992; Fossa et al, 1999a; Kollmannsberger et al, 2000; Hartmann et al, 2003; Salvati et al, 2006; Gremmer et al, 2008; Nonomura et al, 2009). Treatment strategies include chemotherapy, surgical resection, whole-brain radiation therapy, and stereotactic radiosurgery, with most patients receiving multimodal therapy. **Patients with brain metastases at diagnosis should receive BEPx4 chemotherapy followed by resection of residual masses.** The benefit of radiation therapy in this setting is unclear (Fossa et al, 1999a; Kollmannsberger et al, 2000; Hartmann et al, 2003). At our institution, radiation therapy is considered only for patients with unresectable residual lesions not amenable to stereotactic radiosurgery because of concerns of radiation-induced neurotoxicity (Doyle and Einhorn, 2008). **Patients who relapse in the brain after first-line chemotherapy should be treated with second-line chemotherapy followed by resection and/or radiation therapy** (Fossa et al, 1999a; Hartmann et al, 2003). For men who relapse in the brain and at other anatomic sites, the prognosis is very poor, particularly if it is not the first relapse.

KEY POINT: BRAIN METASTASES

- Brain metastases are associated with choriocarcinoma and should be suspected in any patient with a very high serum hCG level. Choriocarcinomas are highly vascular and tend to hemorrhage during chemotherapy, causing intracranial hemorrhage.

Treatment-Related Sequelae

Sequelae of treatment of testis cancer can be divided into late and early complications. Complications from orchiectomy and RPLND are discussed in Chapter 35 and are not reviewed here except to note that the main issues after RPLND are midline scar, ejaculatory dysfunction, small bowel obstruction, and perioperative complications. Also, there is an increased incidence of hypogonadism after orchiectomy for GCT.

Early Toxicity

Cisplatin-based chemotherapy is associated with numerous early complications and side effects, including fatigue, myelosuppression, infection, peripheral neuropathy, hearing loss, diminished renal function, and death. The death rate from toxicity has ranged from 0% to 2.4% during chemotherapy for good-risk disease and from 3% to 4.4% during standard first-line chemotherapy for intermediate-risk and poor-risk disease (de Wit et al, 1998; Nichols et al, 1998, 2001; Toner et al, 2001; Culine et al, 2007, 2008). The impact of chemotherapy and radiation therapy on spermatogenesis has been discussed previously. Most men are able to father children after treatment for GCT but paternity rates are lower for men treated with radiation therapy and/or chemotherapy (Huyghe et al, 2004; Brydoy et al, 2005). Early complications of radiation therapy include fatigue, nausea and vomiting, leukopenia, and dyspepsia (Fossa et al, 1999b; Jones et al, 2005; Oliver et al, 2005).

Late Toxicity

Numerous long-term sequelae have been reported in GCT survivors, including peripheral neuropathy, Raynaud phenomenon, hearing loss, hypogonadism, infertility, SMN, and cardiovascular disease (Brydoy et al, 2009; Fossa et al, 2009; Rossen et al, 2009; Gilligan, 2011). Symptoms of Raynaud phenomenon and peripheral neuropathy have been reported in 20% to 45% and 14% to 43%, respectively, of GCT survivors (Brydoy et al, 2009; Rossen et al, 2009). Significant hearing loss and/or tinnitus after cisplatin-based chemotherapy is reported in 20% to 40% of patients and can be documented via audiometry in 30% to 75%. Hypogonadism has been documented in about 10% to 20% of patients treated with orchiectomy alone, 15% to 40% of patients treated with radiation therapy, and 20% to 25% of patients treated with first-line chemotherapy regimens (Nord et al, 2003; Lackner et al, 2009).

Large population-based studies of GCT survivors have reported an increased risk of death from gastrointestinal and cardiovascular diseases after radiation therapy and an increased risk of death from infections, cardiovascular diseases, and pulmonary diseases after chemotherapy (Fossa et al, 2007). Patients treated with both radiation and chemotherapy have the highest risk of death from nonmalignant causes. The increased cardiovascular disease incidence and mortality in GCT survivors is particularly well documented (Meinardi et al, 2000; Huddart et al, 2003; Fossa et al, 2007; van den Belt-Dusebout et al, 2007; Fossa et al, 2009). The etiologies of these cardiovascular complications are not well understood, but putative contributing factors are radiation-induced or chemotherapy-induced vascular injury and chemotherapy-induced cardiac injury and metabolic syndrome (Nuver et al, 2005; Altena et al, 2009).

The risk of SMN is a particular concern. The incidence of non-germ cell malignancies is 60% to 100% higher in GCT survivors treated with cisplatin-based chemotherapy or radiation

therapy compared with the general population and 200% higher in patients who received both radiation and chemotherapy (Travis et al, 2005; Richiardi et al, 2007). The risk of death from non-germ cell malignancies in GCT survivors treated with radiation or chemotherapy is less well defined but appears to be doubled compared with the general population (Fossa et al, 2004). The frequent use of body CT imaging in the surveillance of patients after therapy is another source of radiation that may increase the risk of SMN (Brenner and Hall, 2007; Chamie et al, 2008; Tarin et al, 2009).

KEY POINT: TREATMENT-RELATED SEQUELAE

- All treatments for GCT (surgery, radiotherapy, and chemotherapy) are associated with risks of early and late toxicity. The most concerning late complications are cardiovascular disease and SMN. With the successful cure of patients (including patients with advanced disease), an important treatment objective is minimizing treatment-related toxicity without compromising curability.

NON-GERM CELL TUMORS**Sex Cord–Stromal Tumors**

Sex cord–stromal tumors are rare, comprising approximately 4% of testis neoplasms. The term *sex cord–stromal tumor* refers to neoplasms containing Leydig cells, Sertoli cells, granulosa cells, or thecal cells. **Approximately 90% of these tumors are benign, and 10% are malignant.** Histologic criteria have been developed to help distinguish between benign and malignant histology and include tumor size larger than 5 cm, necrosis, vascular invasion, nuclear atypia, high mitotic index, increased MIB-1 expression, infiltrative margins, extension beyond the testicular parenchyma, and DNA ploidy (Kim et al, 1985; Cheville et al, 1998). Most malignant cases are associated with two or more of these features. **However, the presence of metastatic disease is the only reliable criterion for making this distinction.**

Leydig Cell Tumors

Leydig cell tumors account for 75% to 80% of sex cord–stromal tumors. There is no association with cryptorchidism. Most of these tumors occur in men 30 to 60 years old, although approximately one fourth occur in children. Adults may present with painless testis mass, testicular pain, gynecomastia (as a result of androgen excess and peripheral estrogen conversion), impotence, decreased libido, and infertility. Boys usually present with a testis mass and isosexual precocious puberty (prominent external genitalia, pubic hair growth, and masculine voice).

Diagnostic workup should include serum tumor markers and testicular ultrasound examination. The ultrasound appearance of these tumors is variable and is indistinguishable from GCT. In the presence of gynecomastia, infertility, depressed libido, or precocious puberty, luteinizing hormone, FSH, testosterone, estrogen, and estradiol should also be drawn (these should be measured after orchiectomy if the diagnosis is not suspected preoperatively). When the diagnosis is confirmed, patients should undergo chest-abdomen-pelvis CT imaging for staging purposes.

In the past, radical inguinal orchiectomy was the initial treatment of choice. If the diagnosis is suspected preoperatively, given the 90% incidence of benign histology, testis-sparing surgery may be considered for lesions less than 3 cm with intraoperative frozen-section histologic confirmation (Carmignani et al, 2006, 2007). Completion orchiectomy should be performed if GCT histology is seen (either on intraoperative frozen section or on final pathology) or if malignant features (listed earlier) are present on final pathologic examination of the resected tumor.

Given the rarity of these tumors, they are often not suspected preoperatively, and most patients undergo radical orchiectomy. Benign lesions are usually small, yellow to brown, and well circumscribed, without areas of necrosis or hemorrhage. Histologically, the tumors consist of uniform, polygonal cells with round nuclei. Reinke crystals are present in 25% to 40% of cases and appear as densely eosinophilic, needlelike or rhomboid structures within the cytoplasm. These tumors must be distinguished from Leydig cell hyperplasia that occur in atrophic testes and adjacent to GCTs, in which Leydig cells infiltrate between seminiferous tubules without displacing or obliterating them. Malignant behavior has not been reported in a prepubertal patient. Older patients are more likely to have malignant tumors.

The most frequent metastatic sites are the retroperitoneum and lung. RPLND is reasonable in selected cases with adverse features, although high rates of progression are observed in cases with pathologically involved nodes, suggesting a staging role only for RPLND (Mosharafa et al, 2003). Metastatic Leydig cell tumors are resistant to chemotherapy and radiation therapy, and survival is poor (Mosharafa et al, 2003). Ortho,para-DDD, a potent inhibitor of steroidogenesis, may produce partial responses in patients with metastasis and excess androgen production, but cure is impossible (Schwarzman et al, 1989). Surveillance is recommended for patients without clinical or pathologic features suggestive of malignancy. There are no widely accepted criteria for follow-up, but patients should be monitored at regular intervals with clinical assessment, hormonal profile (including luteinizing hormone, FSH, testosterone, estrogen, and estradiol), and CT imaging of the chest, abdomen, and pelvis for 2 years. Persistent Leydig cell dysfunction and hypogonadism may occur after excision of the primary tumor, and 40% of men may require testosterone supplementation postoperatively (Conkey et al, 2005).

Sertoli Cell Tumor

Sertoli cell tumors constitute less than 1% of testis neoplasms. The median age at diagnosis is 45 years, but rare cases in boys have been reported. Rarely, these tumors are associated with Peutz-Jeghers syndrome and androgen insensitivity syndrome and are frequently bilateral (either synchronous or metachronous). There is no association with cryptorchidism. Gynecomastia is evident in one third of patients. As for Leydig cell tumors, testis-sparing surgery can be considered for tumors less than 3 cm given the high incidence of benign histology (90%). For tumors larger than 3 cm or if intraoperative frozen-section or final pathologic analysis reveals GCT or malignant features, radical inguinal orchiectomy should be performed. The tumors are well circumscribed, yellow-white or tan, with uniform consistency. Microscopically, the tumors contain epithelial elements resembling Sertoli cells with varying amounts of stroma organized into tubules. These tumors may be misinterpreted as seminomas leading to errors in the selection of treatment. Diagnostic workup; staging studies; and criteria for treatment, surveillance, and follow-up are similar to Leydig cell tumors.

Granulosa Cell Tumors

Granulosa cell tumors of the testis are exceedingly rare. The juvenile type is benign and is the most frequent congenital testis tumor (most frequently occurring in infants <6 months old), accounting for 7% of all prepubertal testicular neoplasms. The adult type resembles granulosa cell tumors of the ovary. Gynecomastia and increased estrogen secretion are common. Testis-sparing surgery may be considered for tumors less than 3 cm if the diagnosis is suspected preoperatively. Otherwise, radical inguinal orchiectomy is recommended. Treatment of the primary tumor is curative because these tumors appear to have limited metastatic potential.

Gonadoblastoma

Gonadoblastoma is a mixed germ cell–sex cord–stromal tumor composed of seminoma-like germ cells and sex cord cells showing

Sertoli differentiation. They occur almost exclusively in patients with gonadal dysgenesis and intersex syndromes. Of affected individuals, 80% are phenotypic females, usually presenting with primary amenorrhea. The remaining patients are phenotypic males, almost always presenting with cryptorchidism (with the dysgenetic gonad in the inguinal or abdominal location), hypospadias, and some form of female internal genitalia. **These tumors should be considered an in situ form of malignant GCT because approximately 50% of patients develop an invasive GCT (usually seminoma, although yolk sac tumor and EC can occur) (Ulbright, 2004).** Gonadoblastomas do not metastasize, but metastasis of the malignant GCT elements may occur. **Bilateral orchiectomy is required because of the risk of bilateral tumors (40%) (Scully, 1970).** For patients with malignant GCT, subsequent workup for metastatic disease with or without treatment should be initiated.

Miscellaneous Testis Neoplasms

Dermoid and Epidermoid Cyst

Dermoid and epidermoid cysts are rare benign neoplasms that are thought to arise from benign germ cells with retained embryonic properties or from displaced metaplastic mesothelial cells (Ye and Ulbright, 2012). Grossly, they are well-circumscribed, unilocular cystic masses filled with keratinized debris that may have a laminated appearance, which gives them the characteristic “onion peel” appearance on ultrasound scan. Dermoid cysts are differentiated from epidermoid cysts by the presence of adnexal structures such as glandular elements, adipose tissue, and cartilage. Dermoid and epidermoid cysts are distinguished from teratoma by the absence of ITGCN in the adjacent testis. Enucleation or partial orchiectomy may be performed, although the lesion should be thoroughly sampled by a pathologist to rule out GCT or ITGCN.

Adenocarcinoma of the Rete Testis

Adenocarcinoma of the rete testis is a rare but highly malignant neoplasm arising from the collecting system of the testis. The usual presentation is a painless testis mass with hydrocele. More than 50% of patients present with metastatic disease, and the overall median survival is 1 year. RPLND may be curative in patients with limited retroperitoneal lymph node metastasis. Chemotherapy and radiation therapy are ineffective.

Secondary Tumors of the Testis

Lymphoma

Primary testicular non-Hodgkin lymphoma is a rare tumor representing only 1% to 2% of all cases of lymphoma. Most commonly, lymphoma involves the testis through dissemination from extratesticular sites (Ulbright, 2004). Of cases, 85% occur in men older than 60 years. Non-Hodgkin lymphoma is the most common testicular neoplasm in men older than age 50. Bilateral testicular involvement occurs in 35% of cases. It usually manifests as a painless testicular mass in an older man. Approximately 25% of men have systemic symptoms (fever, night sweats, weight loss). Central nervous system involvement at diagnosis is reported in 10% of men. The initial treatment is radical inguinal orchiectomy. Men with testicular non-Hodgkin lymphoma should be referred to a hematologist-oncologist for staging investigations and subsequent therapy. Most cases are associated with systemic disease, and the overall prognosis is poor.

Leukemic Infiltration

The testis is a frequent site of relapse in boys with acute lymphocytic leukemia. Most boys are in complete remission at the time of testicular enlargement. The diagnosis can usually be made by biopsy, and orchiectomy is unnecessary. Local control can be achieved with low-dose radiotherapy (20 Gy), and treatment

should include the contralateral testis because of the frequent risk of bilateral involvement. Overall, the prognosis is poor because most patients have associated systemic disease.

Metastases

Metastases to the testis are rare. Bilateral involvement occurs in 15% of patients. The most common primary tumors are prostate, lung, melanoma, colon, and kidney. Although treatment is largely dictated by the primary tumor, orchiectomy may be considered for palliative reasons.

TUMORS OF THE TESTICULAR ADNEXA

Paratesticular tumors are rare and account for approximately 5% of intrascrotal neoplasms, roughly 75% of which arise from the spermatic cord.

Adenomatoid Tumor

Adenomatoid tumor is the most common paratesticular tumor, most commonly involving the epididymis (although these tumors may also arise within the testicular tunicae or the spermatic cord). The most common presentation is a small (0.5 to 5 cm), painless paratesticular mass detected on routine examination in a man in his third or fourth decade. **These tumors are benign and managed by inguinal exploration and surgical excision.** On microscopic examination, tumors are composed of epithelial-like cells that contain vacuoles and fibrous stroma.

Cystadenoma

Cystadenoma of the epididymis corresponds to benign epithelial hyperplasia. The lesions are usually multicystic, and the walls are studded with nodules of epithelial cells arranged in a glandular or papillary configuration. **Approximately one third of cases occur in patients with von Hippel-Lindau disease, which are usually bilateral.** The lesions are usually small and painless and are detected on routine examination in a young man.

Mesothelioma

Paratesticular mesothelioma arises from the tunica vaginalis and usually manifests as a painless scrotal mass in association with a hydrocele. These tumors most commonly occur in older adults but may be encountered in any age group. **Benign and malignant cases have been described, with the distinction based on atypia, mitotic activity, and invasion (Ulbright, 2004).** Malignant cases may be associated with asbestos exposure. **Treatment is radical inguinal orchiectomy.** RPLND may be considered in patients with malignant tumors without widespread metastatic disease. The role of chemotherapy for these tumors is poorly defined.

Sarcoma

Sarcomas of the spermatic cord, epididymis, and testis are the most common genitourinary sarcomas in adults. **Liposarcoma is the most common histologic subtype in adults,** followed by leiomyosarcoma, malignant fibrous histiocytoma, rhabdomyosarcoma, and fibrosarcoma (Coleman et al, 2003; Ulbright, 2004; Dotan et al, 2006; Rodriguez et al, 2014). **Embryonal rhabdomyosarcoma is the most common histologic subtype in men younger than age 30.** Sarcomas most commonly arise from the spermatic cord and are located in the intrascrotal region; primary mesenchymal tumors of the testis are exceedingly rare. These tumors usually manifest as a painless, palpable mass, and most are large (>5 cm in size) (Dotan et al, 2006). Ultrasonography demonstrates a solid mass, although it cannot distinguish between benign and malignant pathology. **Any solid mass in the scrotum external to the tunica albuginea should be explored through an inguinal approach, and a biopsy should**

be performed. Liposarcomas of the spermatic cord in the inguinal canal may be mistaken for inguinal hernia or lipoma, and CT or magnetic resonance imaging is helpful to distinguish between these entities.

Most patients have localized disease at diagnosis. **Sarcomas should be managed initially through an inguinal approach with wide excision of the spermatic cord and testis with high ligation.** Patients with an initial incomplete resection should undergo repeat wide excision (Coleman et al, 2003). The primary pattern of failure is local, particularly for liposarcoma (Ballo et al, 2001; Montgomery and Fisher, 2003; Khandekar et al, 2013). Some authors have advocated for postoperative radiation therapy for all paratesticular sarcomas, particularly for liposarcomas and for tumors for which the adequacy of local control is in doubt (Ballo et al, 2001; Hazariwala et al, 2013). However, the efficacy of this approach is debated (Fagundes et al, 1996; Coleman et al, 2003; Khandekar et al, 2013). Systemic chemotherapy should be given to patients with evidence of retroperitoneal or distant metastases. **In the presence of a normal metastatic evaluation, patients with sarcomas other than liposarcoma should undergo RPLND, and postoperative chemotherapy should be given to patients with retroperitoneal lymph node metastasis (Dang et al, 2013).** Given that the lymphatic drainage of the spermatic cord includes the ipsilateral pelvis, inguinal, and retroperitoneal lymph nodes, treating these areas with lymphadenectomy or radiation therapy should be considered. The long-term survival of men with paratesticular sarcoma is approximately 50%, with liposarcoma having the most favorable prognosis and malignant fibrous histiocytoma and leiomyosarcoma having the least favorable prognosis (Coleman et al, 2003; Rodriguez et al, 2014).

Postchemotherapy Retroperitoneal Lymph Node Dissection in High-Risk Populations

Surgical Outcomes, Functional Considerations, and Complications of Retroperitoneal Lymph Node Dissection

Retroperitoneal Lymph Node Dissection in Unique Situations

Conclusion

In addition to its remarkable chemosensitivity, testicular germ cell tumor (GCT) is among the most surgically curable malignancies. Before the development of effective chemotherapeutic regimens for testicular GCT, investigators at Walter Reed Army Hospital were able to achieve a nearly 50% durable cure rate for patients demonstrating node-positive disease at primary retroperitoneal lymph node dissection (RPLND) (Patton et al, 1959). At the present time, nearly 80% of patients presenting with clinical stage I (CS I) testicular nonseminomatous germ cell tumor (NSGCT) are cured with orchiectomy alone (Warde et al, 2002; Hotte et al, 2010), whereas 60% to 80% of patients with pathologic stage II (PS II) NSGCT can be cured with primary RPLND (Donohue et al, 1993a; Stephenson et al, 2005). In the setting of larger volume metastatic disease requiring induction chemotherapy, approximately 90% of patients with residual retroperitoneal masses are cured by postchemotherapy retroperitoneal lymph node dissection (PC-RPLND) (Donohue et al, 1990). This chapter describes the management decision-making processes, operative techniques, and outcomes for testicular cancer surgery. This chapter provides the urologist with the foundation necessary to manage surgically the primary tumor as well as regional retroperitoneal metastases for all stages of testicular cancer.

MANAGEMENT OF TESTIS MASS

History and Physical Examination, Ultrasonography, and Preorchietomy Evaluation

The presentation of a testicular mass warrants a prompt and thorough investigation. Principal to this evaluation is understanding the temporal development of any associated symptoms, characterizing the scrotal contents with careful physical and ultrasound examination, and obtaining appropriate serologic tests (Robson et al, 1965; Sandeman, 1979; Bosl et al, 1981; Thornhill et al, 1987; Richie, 1993; Honig et al, 1994; Petersen et al, 1999; Jacobsen et al, 2000; Simon et al, 2001). Timely recognition and diagnosis are paramount in the treatment of a given cancer at its earliest and most curable stage (Post and Belis, 1980; Oliver, 1985; Gascoigne et al, 1999; Chapple et al, 2004; Moul, 2007). Physical examination is the most crucial part of the evaluation of the testis mass. Although not mandatory, ultrasound examination can provide important details of tumor characteristics and document radiographically the laterality of the lesion (Horstman et al, 1992; Shah et al, 2010; Goddi et al, 2012). Additionally, documentation

of the characteristics of the contralateral testicle is essential because synchronous testicular masses have been reported in approximately 1% of patients (Bokemeyer et al, 1993; Coogan et al, 1998; Che et al, 2002; Holzbeierlein et al, 2003; Pamentier et al, 2003; Fossa et al, 2005; Hentrich et al, 2005). Obtaining serum tumor marker (STM) values, including α -fetoprotein, human chorionic gonadotropin, and lactate dehydrogenase, aids in solidifying a diagnosis of GCT and serves as a baseline to compare serologic trends after orchiectomy. Placement of a testicular prosthesis at the time of radical orchiectomy should be discussed before surgery.

Radical Orchiectomy

In patients in whom a testicular malignancy is suspected, radical orchiectomy is the diagnostic and therapeutic treatment of choice. The approach is via an inguinal incision, allowing for complete removal of the ipsilateral testis, epididymis, and spermatic cord to the level of the internal inguinal ring.

Technique

The patient is positioned supine on the operating room table. Proper preparation of the skin should encompass the abdomen above the umbilicus cranially, the bilateral mid-to-lower thigh caudally, and the external genitalia through to the perineum posteriorly. After sterile draping of the surgical field, exposure of the ipsilateral anterior superior iliac spine, pubic tubercle, and scrotum is required. Palpation and marking the overlying skin of the external inguinal ring can facilitate orientation of the medial extent of the inguinal canal.

The incision, typically 3 to 5 cm in length, is made with a transverse orientation overlying the inguinal canal following the lines of Langer. In circumstances in which a mass is too large to be delivered through the standard incision, the incision can be extended down along the anterior scrotum in a hockey-stick fashion. When the external oblique fascia is exposed and the external ring is identified, the inguinal canal should be opened along its course laterally for approximately 4 cm. In an obese patient, self-retaining instruments such as a Weitlaner or Gelpi retractor often prove helpful or necessary to provide exposure. With the external oblique fascia open, care should be taken to identify the ilioinguinal nerve for prospective preservation. This structure courses parallel to spermatic cord, typically along the cephalad aspect of its anterior surface. When the nerve is safely displaced, the spermatic cord is mobilized within the canal at the level of the pubic tubercle, where it can be encircled

with a Penrose drain. After division of the external spermatic fascia and cremasteric fibers that surround the spermatic cord, gentle traction can be placed in the cephalad direction to draw the testicle toward the incision. Delivery of the testicle can be facilitated by applying external pressure to the ipsilateral hemiscrotum. After division of the gubernaculum, the spermatic cord is mobilized to the level of the internal inguinal ring until the peritoneal reflection is visualized. At this level, the vas deferens and gonadal vessels are dissected out, ligated, and divided separately. Ligation and division are typically performed with nonabsorbable suture, leaving a 1- to 2-cm suture tail on the stump of the gonadal vessels to facilitate identification at RPLND. Individually ligating the vas deferens from the remainder of the spermatic cord facilitates retrieval of the distal spermatic cord stump during subsequent RPLND because the vas deferens is not taken as part of this specimen.

After irrigation of the wound and close inspection for hemostasis, the ilioinguinal nerve is positioned safely in the floor of the inguinal canal, and closure of the external oblique aponeurosis is performed. A two- or three-layer closure of the subcutaneous and skin layers is completed, and sterile dressings are applied. In general, scrotal support and fluff dressings are helpful to avoid unnecessary scrotal swelling and hematoma formation for the first 48 to 72 hours.

Partial Orchiectomy

Because of the high rate of long-term survivors after testis cancer therapy, functional issues pertaining to treatment-related side effects and preservation of quality of life have emerged (Skakkebaek, 1975; Jacobsen et al, 1981; Klein et al, 1985; Haas et al, 1986; Kressel et al, 1988; Robertson, 1995; Carmignani et al, 2004). **Partial orchiectomy should be considered in patients with a polar tumor measuring 2 cm or less and an abnormal or absent contralateral testicle.** In circumstances in which the malignant nature of the tumor is uncertain, inguinal exploration and excisional biopsy can be done. In general, these operations should be performed in very select patients in whom the benefits of organ preservation are thought to outweigh the risks of local tumor recurrence. In patients with a normal contralateral testis, elective testis-sparing surgery is not advised.

Technique

The approach to partial orchiectomy is identical to the approach of a radical inguinal orchiectomy. The use of ischemia with or without hypothermia has been questioned by some authors and can be omitted if the resection time is limited to less than 30 minutes (Giannarini et al, 2010). With sterile towels draping the field to avoid contamination, intraoperative ultrasonography can be used to facilitate localization of the mass. When the mass is identified, a scalpel can be used to incise the tunica albuginea overlying the mass. When the approach is from the ventral midline, a vertical incision along the long axis of the testis is preferred. Otherwise, incisions localized medial or lateral to the ventral midline should be oriented horizontally to follow the course of the segmental arteries beneath the tunica albuginea.

Once identified, the tumor is enucleated preferably with a small rim of surrounding seminiferous tubules insulating the mass. In the presence of a confirmed GCT, the association of concomitant intratubular germ cell neoplasia in the surrounding parenchyma of the ipsilateral testis warrants consideration for completion radical orchiectomy or adjuvant radiotherapy to the remnant testis to reduce the risk of recurrent disease. Because of this risk, some clinicians choose to omit parenchymal biopsies in the setting of confirmed GCT and recommend treatment of all remnants with radical orchiectomy or adjuvant therapy. If radical orchiectomy is not performed, the tunica is closed with absorbable suture, and the testis is placed back into the dependent portion of the scrotal compartment and secured at three points of internal fixation to the gubernaculum or medial septum of the scrotum.

Adjuvant radiotherapy with a dosage of 18 to 20 Gy is recommended to prevent local tumor recurrence in all patients treated with partial orchiectomy for the management of GCT in a functionally solitary testis (Heidenreich et al, 2001; Krege et al, 2008; Giannarini et al, 2010). In these patients, the only benefit of partial orchiectomy is preservation of Leydig cell function. **Any local recurrence within the ipsilateral testis occurring with or without adjuvant therapy should be managed with completion radical orchiectomy.**

Delayed Orchiectomy

Most testicular cancers are initially diagnosed at the time of orchiectomy. However, in a small subset of patients with widespread and/or symptomatic GCT, the diagnosis is made based on biopsy of a metastatic lesion or empirically based on clinical and serologic features. In these unique settings, initiation of systemic chemotherapy supersedes diagnostic orchiectomy (Ondrus et al, 2001). **Because of high discordance of pathologic response rates within the testis, a delayed orchiectomy is recommended for all patients with NSGCT after induction chemotherapy, even in the setting of a complete response in the retroperitoneum** (Snow et al, 1983; Simmonds et al, 1995; Leibovitch et al, 1996; Ondrus et al, 2001).

The role of delayed orchiectomy is more controversial in patients with presumed primary retroperitoneal/extragenadal GCT. In studies in which biopsy of the testis was performed in these cases, intratubular germ cell neoplasia was seen in 42% of patients (Daugaard et al, 1992). Among such patients who are observed after chemotherapy, approximately 5% develop a metachronous testicular cancer (Hartmann et al, 2001). **Radical orchiectomy has been advocated when the metastatic pattern of retroperitoneal disease lateralizes to the expected distribution of a testicular primary.** In a small cohort series at Indiana University, 71% of patients with presumed extragenadal GCT undergoing a post-chemotherapy delayed orchiectomy had histologic evidence of teratoma or necrosis within the testis, the latter suggesting a burned-out primary or complete response to chemotherapy (Brown et al, 2008). If observation of the testis is elected, monthly self-examinations and periodic physician assessment are warranted.

Postorchiectomy Evaluation

After orchiectomy, review of the pathologic findings along with incorporation of appropriate radiographic and serologic studies is necessary to determine clinical stage. Contrast-enhanced computed tomography (CT) with intravenous and oral contrast agents is the most effective means to accomplish this; however, magnetic resonance imaging may serve as a suitable alternative. Fluorodeoxyglucose-labeled positron emission tomography (PET) and lymphoangiography serve little to no role in the staging of GCTs after initial diagnosis. Similar to the evaluation before orchiectomy, assessment of STM (α -fetoprotein, human chorionic gonadotropin, lactate dehydrogenase) values and trends after orchiectomy completes the initial evaluation before patient counseling regarding management options.

KEY POINTS: MANAGEMENT OF THE TESTIS MASS

- Radical inguinal orchiectomy with high ligation of the spermatic cord is the definitive diagnostic and initial therapeutic step for management of testicular cancer in most cases.
- Partial orchiectomy should be considered only in selected patients with a polar mass measuring 2 cm or less and an abnormal or absent contralateral testicle.
- In the rare patient whose disease is sufficiently advanced/symptomatic to warrant immediate initiation of systemic chemotherapy, delayed orchiectomy should be performed given the potential for residual disease.

RETROPERITONEAL LYMPH NODE DISSECTION

All GCT subtypes demonstrate a propensity for predictable lymphatic spread to the retroperitoneum. Choriocarcinoma has also demonstrated a predilection for hematogenous spread. Depending on the presence and bulk of retroperitoneal disease and STM status, RPLND may be incorporated into management of the testicular GCT in the primary or postchemotherapy setting. Although the approaches and techniques of primary RPLND and PC-RPLND are similar, these are fundamentally distinct surgeries. The rationale for primary RPLND is that, in contrast to most malignancies, testicular GCT is surgically curable in most patients with low-volume regional (retroperitoneal) lymphatic metastases. Conversely, the rationale for performing PC-RPLND in patients with residual retroperitoneal masses is that unresected teratoma and/or viable malignancy predispose the patient to disease progression and death. In this section, we discuss similar technical considerations and exposure for primary RPLND

and PC-RPLND. However, the surgeon must be aware of the aforementioned basic philosophical distinctions between these two surgeries. The retroperitoneal lymph node regions are illustrated in Figure 35-1.

The following list provides definitions of the different subtypes of RPLND that are discussed throughout this chapter:

- **Primary RPLND**—RPLND performed after orchiectomy for CS I or low-volume CS II NSGCT with normal postorchiectomy STMs.
- **PC-RPLND**—RPLND performed after completion of induction systemic chemotherapy. This procedure is generally performed when there is a residual retroperitoneal mass and normal postchemotherapy STMs. At some centers, PC-RPLND is performed even when there is a clinical complete remission (CR) to chemotherapy (discussed later).
- **Salvage PC-RPLND**—PC-RPLND performed after completion of induction and salvage (standard or high-dose) chemotherapy.

Figure 35-1. Retroperitoneal lymph node regions. (© 2016 Section of Medical Illustration in the Office of Visual Media at the Indiana University School of Medicine. Published by Elsevier Inc. All rights reserved.)

- **Desperation PC-RPLND**—PC-RPLND performed despite STM elevation.
- **Reoperative RPLND**—PC-RPLND performed in a patient who has undergone prior primary RPLND or PC-RPLND.
- **Resection of late relapse**—PC-RPLND performed for retroperitoneal recurrence 24 months or later after CR to primary therapy (which may or may not have included RPLND).

Preoperative Planning

We do not recommend bowel preparation or dietary modifications before RPLND. STMs should be checked within 7 to 10 days of surgery. Increased quantities of blood products should be considered for patients requiring more complex resections. Preoperative sperm banking should be offered to patients who desire future paternity if retroperitoneal masses are in the path of the postganglionic sympathetic nerve fibers. It is important for the urologist to have a medical oncology partner who possesses the clinical ability to assess bleomycin toxicity, to limit the dose when necessary and to obtain pulmonary function testing when appropriate before sending the patient to surgery to minimize risk of postoperative acute respiratory distress syndrome. Additionally, the surgeon should ensure that the anesthesia provider is aware of any prior receipt of bleomycin and that he or she is familiar and comfortable with management of these patients. Specifically, low fraction of inspired oxygen (FiO_2) and conservative intraoperative fluid resuscitation are important in minimizing the risk of postoperative lung toxicity (Goldiner et al, 1978; Donat and Levy, 1998).

Preoperative CT scan of the abdomen and pelvis should be thoroughly reviewed at initial consultation and immediately before surgery. A current CT scan of the chest is also required in patients with a history of pulmonary masses, planned concurrent resection of thoracic disease, or other radiographic/serologic evidence of disease progression. We prefer that preoperative imaging be performed within 6 weeks of that surgery date. Careful inspection of imaging can usually prevent unplanned intraoperative consultations of other surgical specialists. Preoperative identification of total inferior vena cava (IVC) thrombosis is important because the operation is made simpler by resection of the IVC (Beck and Lalka, 1998). Patients with incomplete occlusion requiring IVC resection may require reconstruction with a cadaveric allograft.

Surgical Technique

An orogastric tube is sufficient for intraoperative gastric decompression. Nasogastric tubes are generally reserved for patients with duodenal invasion that requires resection/repair or high-volume retroperitoneal masses that require complete mobilization of the mesentery and placement of the bowels on the patient's chest for the duration of the surgery.

The patient is placed in the supine position, and a ventral midline incision is made. When the peritoneal cavity is entered, a thorough inspection of abdominal viscera is performed. The falciform ligament is identified, ligated, and divided to minimize risk of hepatic retraction injury. A self-retaining retractor is then placed.

Exposure of the Retroperitoneum

For smaller paracaval and interaortocaval masses, the root of the mesentery is opened from the inferior tip of the cecum to the medial aspect of the inferior mesenteric vein (Fig. 35-2, green dotted line). In the case of large interaortocaval and/or paracaval masses, the mesenteric incision can be continued around the inferior portion of the cecum to the right white line of Toldt and up to the foramen of Winslow to permit placement of the bowels on the chest (see Fig. 35-2, right purple dotted line). In the case of larger left para-aortic masses, the inferior mesenteric vein is often ligated and divided to improve exposure of the left retroperitoneum (see Fig. 35-2, left purple dotted line). Alternatively, in the case of a modified left template dissection for CS I disease, the para-aortic packet can

Figure 35-2. Exposure of the retroperitoneum. IMA, inferior mesenteric artery; IMV, inferior mesenteric vein. (© 2016 Section of Medical Illustration in the Office of Visual Media at the Indiana University School of Medicine. Published by Elsevier Inc. All rights reserved.)

be approached through the left white line of Toldt (see Fig. 35-2, red dotted line).

The plane between the mesentery and the retroperitoneal fat is developed by identifying the gonadal vein and developing the plane along its anterior surface. The duodenum is dissected off of the IVC and left renal vein. Before placing retractors in this region, the superior mesenteric artery must be identified (usually by palpation). The blades of the retractors should then be placed on either side of the superior mesenteric artery.

Split and Roll Technique

The large lymphatics coursing over the left renal vein should be ligated and divided. When the chosen template includes splitting over both great vessels, we prefer to perform the split on the aorta first rather than the IVC to avoid precaval right-sided accessory lower pole renal arteries. The advantage of performing the IVC split first is that the right-sided postganglionic sympathetic nerve fibers can be identified and traced to the superior hypogastric plexus minimizing risk of injury during the aortic split. The split is started at the 12 o'clock position of the aorta, immediately inferior to the left renal vein (Fig. 35-3), and continued caudally taking care to identify prospectively the inferior mesenteric artery (IMA) and (1) preserve it in cases of right modified template RPLND or (2) doubly ligate and divide this structure to expose the left para-aortic region in cases of full bilateral dissection. If a nerve-sparing technique is to be performed, the split should be stopped at the IMA, and postganglionic sympathetic fibers should be identified before proceeding caudally.

Figure 35-3. The split-and-roll technique. IMA, inferior mesenteric artery. (© 2016 Section of Medical Illustration in the Office of Visual Media at the Indiana University School of Medicine. Published by Elsevier Inc. All rights reserved.)

Left Para-aortic Packet

As mentioned previously, the left para-aortic packet can be approached laterally through the left white line of Toldt or medially through the mesenteric root depending on which template is used. The left gonadal vein is doubly ligated and divided where it crosses the left ureter. The ureter is swept laterally and placed behind a retractor to minimize risk of subsequent injury. The split is continued down the 12 o'clock position of the aorta and left common iliac artery until the left ureter is reached. The lymphatic tissue is rolled laterally off of the aorta and left common iliac artery. The three left-sided lumbar arteries located between the renal hilum and aortic bifurcation are identified, doubly ligated, and divided.

The packet is rolled inferiorly off of the left renal vein. The left gonadal and lumbar vein (when present) are doubly ligated and divided where they drain into the left renal vein. The lateral aspect of the packet is dissected off of the lower pole of the kidney and ureter.

The caudal extent of the packet is rolled superiorly off of the posterior body wall. The left genitofemoral nerve and sympathetic

trunk should be identified and preserved when possible. The lumbar veins and body wall ends of the divided lumbar arteries should be identified and controlled. The packet is rolled up to the crus of the diaphragm. Lymphatics should be ligated as they course through the crus and into the retrocrural region. When the para-aortic resection is complete, tension on the ureteral retractor should be released to prevent prolonged ischemia.

Interaortocaval Packet

If a right-sided nerve-sparing technique is to be performed, the IVC split and roll is performed next. Otherwise, the medial side of the aorta can be controlled first. The IVC split is performed from the renal hilum to the crossover of the right common iliac artery where it is continued inferolaterally until the right ureter is reached. The right gonadal vein is doubly ligated and divided at the IVC. The lymphatic tissue is rolled medially off of the IVC. The nerves are visible running obliquely along the lateral edge of the packet as it is peeled off the medial border of the IVC. The lumbar veins located between the renal hilum and the

common iliac veins are identified, doubly ligated, and divided. In contrast to the lumbar arteries, the number and positions of the veins are unpredictable. When the medial aspect of the IVC has been controlled, lymphatic tissue is rolled laterally off of the IVC, and any lumbar veins encountered are ligated and divided. Before harvesting the interaortocaval packet, the right gonadal vein is ligated and divided where it crosses the right ureter. The ureter is placed behind a retractor to keep it out of the field of dissection.

Lymphatic tissue is rolled medially off of the aorta. The medial three lumbar arteries are identified, ligated, and divided (Fig. 35-4C). The interaortocaval lymph node packet is harvested off of the anterior spinous ligament. The right sympathetic trunk is encountered at the right lateral border of the interaortocaval packet and should be preserved when possible. As the packet is rolled off of the anterior spinous ligament, the cut ends of the lumbar vessels should be controlled as they enter and exit the body wall. The superior aspect of the packet is rolled inferiorly off of the renal vessels exposing the crus of the diaphragm. Taking care to avoid injury to the renal artery, the lymphatics coursing into the retrocrural region must be ligated to prevent postoperative lymph leak and chylous ascites.

Right Paracaval Packet

The right paracaval packet tends to be the smallest of the three major lymph node packets because the right kidney and ureter are located very close to the lateral border of the IVC. The lymphatic tissue is rolled laterally and superiorly off of the right common iliac artery until the crossover of the right ureter is reached. The tissue is rolled superiorly off of the psoas fascia, taking care to preserve the right sympathetic trunk and the genitofemoral nerve. This roll is continued superiorly toward the right renal hilum and crus of the diaphragm. This packet often tapers to nothing and crosses under the IVC before the actual renal hilum is reached.

Gonadal Vein

The peritoneal lining is opened immediately over the gonadal vein. The ureter should be swept posteriorly off of the vein. The gonadal vein is placed on gentle traction and bluntly dissected down to the internal ring. If the orchiectomy was performed properly, the distal cut end of the gonadal vein and suture ligature should be easily retrievable. When the left gonadal vein is approached through the mesenteric root, it must be passed under

the mesentery of the sigmoid colon before it is resected down to the left internal inguinal ring.

Nerve-Sparing Technique

The anatomy of the four postganglionic efferent sympathetic fibers (L1 through L4) involved in antegrade ejaculation demonstrates significant variability from patient to patient. The L2 and L3 fibers are usually fused. Although the L2 through L4 fibers tend to take a more anterior course along the aorta and common iliac vessels, the L1 fiber takes a more shallow, caudal, and oblique course, exiting the sympathetic trunk near the level of the ipsilateral renal hilum. An intraoperative photograph of the bilateral nerve-sparing technique is shown in [Figure 35-5](#).

The left-sided postganglionic sympathetic nerves are first identified as they course along the lateral border of the aorta and left common iliac artery and onto the anterior surface of these vessels immediately caudal to the IMA (see [Fig. 35-4B](#)). A Kittner sponge can be used to sweep the fatty connective tissue gently away revealing the shiny off-white nerve fibers running obliquely over the aorta and joining the contralateral postganglionic fibers in the superior hypogastric plexus. Fibers can be tagged with vessel loops to provide continued gentle traction as they are dissected to their origins at the sympathetic trunk. Alternatively, the left sympathetic trunk can be identified first distal to the level of the IMA and traced cranially until the postganglionic fibers are sequentially encountered.

The right-sided postganglionic nerve fibers are best identified as the precaval and interaortocaval lymphatic tissue is rolled medially off of the IVC. The postganglionic fibers can be seen coursing obliquely in an anterior and inferior direction toward the superior hypogastric plexus (see [Figs. 35-4A and 35-5](#)). These can be cleared of overlying tissue using a Kittner sponge. As described previously, the individual fibers should be encircled with vessel loops to place them on traction as they are traced down to their origins in the right sympathetic trunk.

When the nerve fibers have been dissected free for the entirety of their courses through the RPLND template, the lymphatic packets

around the fibers should be dissected. The specimen must be sequentially passed through the web of postganglionic fibers as it is released from the body wall. Care must be taken to avoid injuring the fibers during specimen harvest and obtaining hemostasis. The nerve fibers often exit the sympathetic trunks in close proximity to the lumbar vessels, which puts them at particular risk of collateral injury if lumbar bleeding is encountered.

Closure and Postoperative Care

When the RPLND is complete, the resection bed should be carefully inspected for any residual lymphatic tissue, lymph leaks, and hemostasis. Lymph leaks can be controlled with placement of metal clips. The abdomen should be copiously irrigated with warm sterile water in an attempt to discover any bleeding vessels in spasm. The posterior parietal peritoneum should be reapproximated with a simple running 2-0 chromic suture. This maneuver is designed to prevent the small bowel from scarring to the great vessels and retroperitoneum. Additionally, in the setting of full mobilization of the root and ascending colon, reapproximation of the mesentery is thought to decrease the risk of volvulus. When the retroperitoneum is closed, the small bowel should be run for its entire length to rule out unrecognized retractor injuries. Additionally, the liver, colon, and stomach should be inspected. Surgical drains are not routinely placed. However, large-volume retroperitoneal, retrocrural, or duodenal resections may require a drain. We leave a Penrose drain for large-volume resections, given the propensity of postoperative abdominal third spacing. This drain is typically removed after the patient has resumed a regular diet and drainage remains serous and less than 100 mL for 24 hours.

In the absence of bowel repair/anastomoses, patients are given sips of ice chips on the evening of surgery. On postoperative day 1, patients are advanced to unlimited clear liquids, and they are encouraged to spend most of the day in a chair and ambulating. If patients tolerate clear liquids, they are advanced to a regular diet and transitioned off of intravenous pain medications on postoperative day 2. Patients are typically discharged between postoperative days 3 and 5 depending on how quickly they are able to tolerate a

Figure 35-5. Bilateral nerve-sparing technique. IVC, inferior vena cava; L., left; L1 through L4, right-sided postganglionic sympathetic nerves.

regular diet. Patients undergoing larger resections tend to have longer inpatient stays.

AUXILIARY PROCEDURES

The following discussion of auxiliary procedures applies to PC-RPLND because these procedures are rarely, if ever, required during primary RPLND. The incidence of auxiliary procedures at the time of PC-RPLND ranges from 24% to 45% in the literature (Beck et al, 2009; Heidenreich et al, 2009; Winter et al, 2012). The most common auxiliary procedure is a nephrectomy, followed by vascular reconstruction or resection. As the volume of retroperitoneal disease increases, so does the likelihood of requiring resection of adjacent organs and/or structures.

Nephrectomy

Nephrectomy at the time of PC-RPLND is the most commonly performed auxiliary procedure. The incidence of nephrectomy at PC-RPLND ranges from 5% to 31% (Base and Navratil, 1984; Beck and Lalka, 1998; Nash et al, 1998; Stephenson et al, 2006; Djaladat et al, 2012; Cary et al, 2013). Table 35-1 summarizes studies reporting on simultaneous nephrectomy and associated risk factors.

Recognition of preoperative risk factors associated with nephrectomy at PC-RPLND is vital for surgical planning and patient counseling. Nephrectomy is usually needed in high-risk settings such as salvage RPLND, desperation RPLND, resection of late relapse, or reoperative RPLND. Additional risk factors include retroperitoneal mass size and location of primary tumor (i.e., left vs. right testicle). In the Indiana University study, men with retroperitoneal mass size greater than 10 cm had a ninefold increase in odds of nephrectomy compared with men with retroperitoneal mass less than 2 cm. Left-sided primary tumors with left para-aortic retroperitoneal masses had significantly increased odds of nephrectomy compared with right-sided tumors (odds ratio 5.44, $P < .0001$) (Cary et al, 2013). Other reports supported this finding (Heidenreich et al, 2009; Djaladat et al, 2012). This finding is due to the fact that left-sided primary tumors metastasize to the para-aortic region near the renal hilum compared with metastasis of right-sided primary tumors to the interaortocaval landing zone.

It is important to consider postoperative renal function after nephrectomy because these patients may require postoperative

adjuvant chemotherapy. Studies from Indiana University and Memorial Sloan-Kettering Cancer Center (MSKCC) reported a decline in renal function after nephrectomy (Nash et al, 1998; Stephenson et al, 2006). However, this decreased renal function neither resulted in the need for renal replacement therapy nor compromised subsequent adjuvant or salvage chemotherapy when necessary. Despite changes in renal function, most patients are able to tolerate subsequent chemotherapy if needed and avoid renal replacement therapy.

Major Vascular Reconstruction

Inferior Vena Cava Resection

Most cases requiring IVC resection have bulky stage disease (stage IIb or higher). The incidence of IVC resection reported in the literature ranges from 5% to 10% (Beck and Lalka, 1998; Nash et al, 1998; Winter et al, 2012). In 1991, Donohue and colleagues reported 40 patients who underwent IVC resection without reconstruction. In this study, the three indications for caval resection were necessity for tumor clearance (38%), vena caval scar occlusion (14%), and vena caval tumor thrombus (48%). The decision for en bloc caval resection was justified by the adverse nodal pathology, which included active cancer in 63% and teratoma in 31% of the specimens. For patients with lower extremity edema and imaging concerning for IVC compression/occlusion, venacavography, ultrasonography, or magnetic resonance imaging is helpful to assess for flow through the IVC and guide intraoperative decision making.

A German study reported on 34 patients with IVC interventions during PC-RPLND (Winter et al, 2012). There were 23 complete IVC resections performed with four patients having an IVC reconstruction using a polytetrafluoroethylene graft. The authors found that retroperitoneal mass size ($P < .0001$) and International Germ Cell Cancer Collaborative Group (IGCCCG) intermediate/poor risk ($P = .005$) were associated with the need for an IVC intervention on univariate analysis. The probability for an IVC intervention was 20.4% for patients with retroperitoneal mass size 5 cm or larger and IGCCCG intermediate/poor risk. Conversely, patients with retroperitoneal mass size smaller than 5 cm and good-risk disease had only a 2.7% probability for an IVC intervention.

Routine reconstruction of the vena cava after resection is not required. Data on 65 infrarenal IVC resections without reconstruction by Beck and Lalka (1998) support this approach. This study

TABLE 35-1 Risk Factors and Indications for Nephrectomy at Postchemotherapy Retroperitoneal Lymph Node Dissection*

evaluated the long-term sequelae of IVC resection using a survey developed by an international consensus conference on chronic venous disease held by the American Venous Forum (Beebe et al, 1996). The median follow-up for these patients was 89 months. Of patients, 75% had a disability score of 0 to 1 (none or mild disability). Only one patient had the highest possible disability score. Although these patients are at higher risk for chylous ascites and other periprocedural complications (Baniel et al, 1993), long-term venous congestion seems to be less of an issue; this is particularly true if there is complete occlusion with development of collateral circulation present preoperatively. Slow progressive retroperitoneal tumor growth with accompanying desmoplastic reaction to chemotherapy likely results in a gradual occlusion of caval blood flow allowing for adequate development of venous collateral circulation. The development of this collateral venous return likely results in less morbidity from caval resection in patients with testis cancer compared to patients with acute IVC occlusion.

Aortic Resection and Reconstruction

In some cases, retroperitoneal tumor encasement of the aorta requires en bloc aortic resection with reconstruction to remove the retroperitoneal mass adequately. **When this clinical situation occurs, it is crucial to alert additional surgical teams (i.e., vascular surgery) preoperatively to ensure successful clinical outcomes.** It is ideal to anticipate the need for aortic replacement preoperatively to allow proper patient counseling and time to coordinate between surgical services. An aortic tube graft is most commonly used for reconstruction; however, an aortobi-iliac graft may be used depending on the extent of tumor involvement.

Several studies evaluated the indications for aortic resection and its morbidity. In 2001, Beck and colleagues reported 15 patients who underwent aortic replacement during PC-RPLND. **Over a 30-year span involving more than 1200 patients, approximately 1% required this procedure.** Two thirds of these patients had received at least one course of salvage chemotherapy and/or had elevated STMs at the time of surgery. The indication for aortic replacement in these patients was tumor fixation to the aorta, with en bloc resection of the aorta deemed necessary for complete tumor removal. The retroperitoneal pathology in this group revealed active cancer in 80% and teratoma in 20%. At a median follow-up of 34 months, 33% of these patients were disease-free. Given the chemoresistant nature of the disease and bulky tumor burden surrounding the aorta in most of these patients with advanced GCT, aortic resection is a worthwhile undertaking and may provide a therapeutic benefit in a significant proportion of patients. In a multi-institutional German study of 402 patients who underwent PC-RPLND, 6 patients required aortic resection with graft placement (Winter et al, 2012). Although not statistically significant, there was a trend toward aortic replacement occurring more commonly in patients with residual mass size 5 cm or larger and having IGCCCG intermediate/poor risk.

When the decision for aortic resection has been made, the principles of the operation do not change substantially. The IVC should be dissected away from the mass and aorta using the split-and-roll technique with division of lumbar veins. The left ureter should be freed from the retroperitoneal mass. If the tumor does not encroach on the left renal hilum, this is also dissected free. The vascular surgery team assists with this dissection to ensure adequate length of the aorta cranial and caudal to the tumor, which allows for proximal and distal vascular control and ease of graft anastomoses. The aorta is cross-clamped and resected en bloc with the retroperitoneal mass. Lumbar arteries are divided during this process. Before cross clamping, the patient is usually administered intravenous heparin to minimize the risk of arterial thrombosis. The graft is sewn into place using standard vascular surgery principles.

Hepatic Resections

Patients with hepatic involvement at initial presentation fall into the IGCCCG poor-risk classification. Based on the initial 1997

publication of the IGCCCG risk stratification scheme, patients in this risk category have a 5-year overall survival (OS) of 48%. Patients with liver metastasis represent approximately 6% of patients with advanced GCTs (International Germ Cell Consensus Classification, 1997).

Jacobsen and colleagues (2010) evaluated the concordance between retroperitoneal and liver histology in patients who largely underwent simultaneous resections. The authors identified 59 patients with advanced GCT who underwent a liver resection. Of all hepatic specimens, 73% contained necrosis only, and the histologic concordance between retroperitoneal and liver necrosis was 94%. The authors concluded that management of hepatic lesions must be individualized, but that observation may be warranted for liver lesions requiring complicated hepatic surgery. Conversely, other groups found the histologic concordance between the retroperitoneum and liver less reliable (Hartmann et al, 2005; You et al, 2009). Nevertheless, necrosis is the most common histology found in the liver after chemotherapy in these studies. **Observation of liver lesions is warranted in some cases, particularly when hepatic involvement may require extensive resection.** Use of intraoperative frozen-section analysis of core biopsy specimens of liver lesions may provide additional information when deciding whether or not to resect hepatic lesions.

Pelvic Resections

Pelvic lymph node dissection is rarely needed during PC-RPLND. The largest series to date on pelvic metastases among patients undergoing RPLND was presented as an abstract on 137 (5%) of 2722 patients treated from 1990 to 2009. Mean pelvic mass size was 6.5 cm. The pelvic mass was managed by pelvic excision alone in 28%, pelvic excision with primary RPLND in 3%, and pelvic excision with PC-RPLND in 69%. Pelvic pathology revealed necrosis, sarcoma, teratoma, and active cancer in 16%, 5%, 55%, and 24%. **Factors associated with pelvic metastases were initial clinical stage, extragonadal primary, and prior groin surgery (e.g., inguinal hernia repair) (all $P < .001$) (Mehan et al, 2011).**

MSKCC reported their findings on 44 (2%) patients who underwent pelvic lymph node dissection during the course of management (Alanee et al, 2013). Mean pelvic mass size was 4 cm. Pelvic histology in this series revealed active cancer in 19 (43%) and teratoma in 17 (39%). No patient reported a history of prior scrotal or inguinal surgery. Overall, the need for pelvic lymph node dissection is rare; approximately 80% of patients with a pelvic mass had either teratoma or active cancer on final histology warranting resection in patients with pelvic disease.

Management of Supradiaphragmatic Disease

Approximately 10% to 20% of patients with a diagnosis of testicular cancer have evidence of supradiaphragmatic disease at presentation or go on to manifest intrathoracic spread at some point in the course of their illness (Kesler et al, 2011). Pulmonary metastases of testicular GCT represent disease spread via the hematogenous route, whereas mediastinal and cervical metastases represent lymphatic spread. Approximately 80% of mediastinal metastases are confined to the lower (retrocrural) and middle visceral mediastinum (Kesler et al, 2011). GCT found in the anterior mediastinum usually indicates a mediastinal primary GCT.

Studies evaluating comparative histology of retroperitoneal and thoracic disease have demonstrated pathologic discordance ranging from 25% to 50%. Most of these patients harbor the more aggressive pathology in the retroperitoneum (Gerl et al, 1994; Gels et al, 1997; Steyerberg et al, 1997; Besse et al, 2009). Steyerberg and colleagues (1997) reported on a multi-institutional study of 215 patients undergoing thoracotomy after cisplatin-based induction chemotherapy in an attempt to predict thoracic histology. RPLND histology was a strong predictor of histology at thoracotomy with 89% of patients with necrosis at RPLND having necrosis only in the chest. **It is generally recommended that if these resections are to be staged, RPLND should be performed first because the finding**

of retroperitoneal necrosis/fibrosis may spare select patients unnecessary thoracic resection. Determining if and when to proceed with resection of thoracic disease in the setting of retroperitoneal necrosis is a decision that needs to be based on the expertise of a multidisciplinary testicular cancer team that has extensive experience in dealing with this disease. Kesler and colleagues (2011) recommended resection of any residual postchemotherapy thoracic mass larger than 1 cm. The exception to this rule would be a patient with extensive residual masses requiring a potentially morbid resection in the setting of necrosis only at RPLND.

Resection of Retrocrural Disease

Description of the surgical approach to most supradiaphragmatic disease is beyond the scope of this chapter. However, the surgical approach to and timing of resection of retrocrural disease is often intimately related to RPLND. The retrocrural space presents a surgical challenge given its anatomic location, and surgical approaches to retrocrural disease have evolved over time. Most of these cases are performed in combination with the thoracic surgery team. At Indiana University, early efforts employed a thoracoabdominal incision or a separate midline laparotomy and posterior thoracotomy. A more recent technique used for residual lower retrocrural disease is a midline laparotomy employing a transabdominal transdiaphragmatic approach that can be performed at the same time as RPLND (Fig. 35-6). This approach was first described by Fadel and associates (2000) in 18 patients who had simultaneous resection of masses located in the retroperitoneum and lower mediastinum. The rationale for this approach was to minimize the morbidity of a thoracotomy when feasible. Kesler and colleagues (2003) published results on 268 patients with mediastinal metastases who underwent mediastinal dissection for NSGCT. A transabdominal transdiaphragmatic approach was used in 60 (13.2%) of these patients. Operative morbidity was low with three (1.1%) operative deaths in the entire cohort, which represented patients with extensive/bulky residual disease.

The timing of retrocrural resection depends in part on whether there is contiguous disease in the retroperitoneum. Generally, if

small-volume retrocrural disease exists concurrently with a retroperitoneal mass, this is approached through a single transabdominal and transdiaphragmatic incision simultaneously. If large-volume retroperitoneal teratomatous disease exists requiring a prolonged surgical time for RPLND, the retrocrural and mediastinal resection can be staged. If the mediastinal disease is not contiguous, the timing of mediastinal dissection is guided in part by the pathology of the retroperitoneum. This rationale is based on studies evaluating concordance between retroperitoneal and thoracic pathology discussed earlier.

KEY POINTS: AUXILIARY PROCEDURES

- Nephrectomy is the most commonly required auxiliary procedure. It is more common with large left-sided masses and when PC-RPLND is performed in high-risk settings.
- Routine IVC reconstruction is unnecessary when en bloc resection is performed in the setting of complete or near-complete IVC occlusion.
- Given the complex vascular reconstruction required, every effort must be made preoperatively to identify patients who require en bloc aortic resection.
- Given the high incidence of necrosis, the decision to proceed with hepatic resection needs to be based on retroperitoneal pathology (when available) and predicted morbidity of hepatic resection as determined by hepatic surgical specialists.
- Pathologic discordance between retroperitoneal and thoracic disease is common, with more aggressive histology being found more commonly in the retroperitoneum. If procedures are to be staged, RPLND should be performed first.
- When patients harbor residual masses in the retroperitoneum and the retrocrural region, consideration should be given to simultaneous PC-RPLND and retrocrural resection using a transabdominal, transdiaphragmatic approach to the latter.

SURGICAL DECISION MAKING

This section discusses the decision-making process involved in determining when to perform RPLND, the extent of dissection, and when to administer postoperative chemotherapy. The indications for, advantages of, and disadvantages of primary RPLND are discussed in Chapter 34 and are not repeated here.

Management of Clinical Complete Remission to Induction Chemotherapy

There is little debate that patients with disseminated testicular cancer who achieve a complete serologic remission but harbor a residual retroperitoneal mass after induction chemotherapy require PC-RPLND. However, the management of patients who achieve complete radiographic (no residual mass >1 cm) and serologic remission of metastatic GCT is controversial. Approximately 70% of men who receive cisplatin-based chemotherapy for stage II or higher testicular cancer can be expected to demonstrate complete resolution of measurable disease. Management options for these patients include observation or PC-RPLND.

Proponents of observation cite the excellent long-term survival demonstrated by patients managed nonoperatively. In a study of 141 men observed after demonstrating clinical CR to induction chemotherapy alone, Ehrlich and associates (2010) reported 15-year recurrence-free survival (RFS) of 90% and cancer-specific survival (CSS) of 97%. In a similar study of 161 patients with median 4.5-year follow-up, Kollmannsberger and colleagues (2010) reported RFS of 93.8% and CSS of 100%.

Investigators at MSKCC recommended performing PC-RPLND on all patients with a history of retroperitoneal metastases even in the setting of a clinical CR because of the potential for residual microscopic disease. In 2006, Carver and coworkers reported on 532 patients undergoing PC-RPLND at MSKCC. Of 154 patients demonstrating a residual mass 1 cm or smaller on cross-sectional imaging performed after chemotherapy, 22%, 1%, and 5% demonstrated teratoma, teratoma/GCT, and GCT at PC-RPLND.

The main issue at the center of this debate is the natural history of microscopic residual teratoma. The concerns expressed by proponents of PC-RPLND in patients with clinical CR is that microscopic teratoma left in the retroperitoneum may lead to growing teratoma syndrome, late relapse, or malignant transformation to somatic-type malignancy. Proponents of observation propose that microscopic teratoma is biologically inert in most cases. Table 35-2 lists the results of three retrospective studies evaluating these two management strategies for patients with clinical CR to chemotherapy alone. Survival outcomes were excellent using either approach (Karellas et al, 2007; Ehrlich et al, 2010; Kollmannsberger et al, 2010). The two questions that remain to be answered are: (1) Does performing PC-RPLND in these patients prevent cancer-specific deaths? (2) Would the number needed to treat to prevent one death be low enough to justify this approach?

Use of Modified Templates in Primary Retroperitoneal Lymph Node Dissection

As the patterns of lymphatic spread of GCT have been defined, various RPLND templates have been proposed with the goal of balancing therapeutic efficacy with potential morbidity. Historically, RPLND involved removal of all lymphatic tissue contained in a contemporary bilateral infrahilum template in addition to resection in the interiliac region down to the bifurcation of the common iliac vessels (Ray et al, 1974). Full bilateral suprahilum dissections were performed routinely at some centers as well (Donohue et al, 1982a). Sometimes performed through a large thoracoabdominal incision, these resections were necessary to provide the best chance for durable cure because of the absence of curative chemotherapy for GCT and were associated with significant perioperative morbidity as well as rendering most patients anejaculatory (Donohue and Rowland, 1981).

In the 1970s and 1980s, the development of curative cisplatin-based chemotherapeutic regimens (Einhorn and Donohue, 1977), elucidation of distinct lymphatic spread for right-sided versus left-sided testicular tumors (Ray et al, 1974; Donohue et al, 1982b; Weissbach and Boedefeld, 1987), and description of surgical techniques to preserve the postganglionic sympathetic nerve fibers involved in seminal emission and antegrade ejaculation (Jewett et al, 1988; Colleselli et al, 1990; Donohue et al, 1990) significantly altered management of the retroperitoneum in patients with testicular GCT. In 1974, Ray and colleagues presented a series of 283 patients undergoing RPLND at MSKCC from 1944 to 1971. Dissections were predominantly infrahilum and evolved from a full bilateral dissection to a “modified bilateral” dissection as the primary landing zones of right-sided versus left-sided primaries became apparent. These modified bilateral templates were very similar to modified unilateral templates with the exception that lymphatic tissue below the IMA was routinely resected. The detailed description of distinct templates based on the laterality of the testicular primary was the first of its kind and set the stage for further refinement.

Donohue and colleagues (1982b) published a pathologic lymph node mapping study performed at Indiana University on 104 patients found to have pathologically positive nodes (pN+) at primary RPLND. Full bilateral dissections to include bilateral suprahilum dissections were performed on every patient. Investigators found that left-sided tumors were most likely to metastasize to the left para-aortic lymph nodes, whereas right-sided tumors were most likely to metastasize to interaortocaval and precaval regions. Spread to contralateral retroperitoneum and suprahilum regions was rare but increased with tumor bulk. Metastasis to the interiliac region was rare. This study confirmed the relatively predictable pattern of the lymphatic spread of testicular GCTs and provided strong pathologic evidence for the use of “modified bilateral” templates proposed by Ray and colleagues (1974) in patients with low-stage retroperitoneal disease. Omission of the contralateral retroperitoneum and interiliac regions resulted in the preservation of antegrade ejaculation in most patients. Omission of suprahilum regions decreased the risk of

postoperative chylous ascites, renovascular injuries, and pancreatic complications.

In 1987, Weissbach and Boedefeld reported a multi-institutional retrospective review of 214 patients with nonbulky PS II disease. The authors recommended a more reduced left-sided template including the para-aortic and upper preaortic nodes. The authors also proposed that a frozen section be sent from the primary landing zone; if the section was positive, a full bilateral infrahilar RPLND should be performed.

The end result of these template studies has been a more efficient, less morbid, and maximally effective RPLND. There is still significant debate among experts regarding the ideal extent of surgical templates. Most experts agree that suprahilar/retrocruar and interiliac resections can safely be omitted from the standard RPLND template. However, controversy exists regarding the need to resect the contralateral retroperitoneal lymphatic tissue. The boundaries of the modified unilateral templates and a full bilateral template are demonstrated in Figure 35-7.

Eggner and colleagues (2007b) reviewed a series of 500 patients undergoing primary RPLND for CS I or IIA testicular cancer at MSKCC. Bilateral infrahilar dissection was usually performed. The authors analyzed the 191 patients (38%) with PS II disease for the anatomic distribution of positive-node packets and applied five modified templates to these results. They reported that 3% to 23% of patients with pathologically positive nodes were found to have disease outside of the modified unilateral template depending on which one was applied. Extratemplate disease was seen more commonly with right-sided than left-sided tumors. Given these results, the authors recommended full bilateral infrahilar nerve-sparing RPLND for patients with CS I or IIA testicular cancer.

To date, no prospective or retrospective studies have compared the modified unilateral templates with the full bilateral templates. As discussed earlier, CSS and OS approach 100% in all series. Expanding the templates cannot be expected to improve either of these outcomes. The question is whether performance of a full bilateral infrahilar RPLND would prevent

retroperitoneal relapses that would occur after a properly performed modified unilateral template. When comparing series from centers that use the modified unilateral templates with series from centers that use the bilateral infrahilar templates, outcomes are very similar (Table 35-3) (Donohue et al, 1993a; Hermans et al, 2000; Nicolai et al, 2004; Stephenson et al, 2005). Although the MSKCC series reported an increased proportion of patients being cured by surgery alone, patients with pN2 disease routinely receive adjuvant postoperative chemotherapy at that center (Stephenson et al, 2005). In the first Indiana study, most of the node-positive patients were randomly assigned to observation versus adjuvant chemotherapy on protocol (Donohue et al, 1993a). In the more recent Indiana study, pN1 patients and most pN2 patients were observed with chemotherapy reserved for patients who experienced recurrence and pN3 patients (Hermans et al, 2000).

The appropriate boundaries of the primary RPLND template are controversial. Use of the templates recommended in the studies by Ray, Donohue, Weissbach, and Eggner and their colleagues will undoubtedly result in excellent survival outcomes. The question of which template offers greatest balance of oncologic control and minimization of morbidity remains unanswered.

Use of Modified Templates in Retroperitoneal Lymph Node Dissection after Chemotherapy

Donohue and colleagues first reported their experience performing consolidative RPLND after cisplatin-based chemotherapy in 1982. Most tumors containing teratoma and/or viable malignancy were located in their respective primary landing zones. However, given the frequent contralateral crossover in the setting of bulky disease and the inability to obtain reliable confirmation of histology intraoperatively, the authors stressed the importance of the PC-RPLND being "as complete as possible" (Donohue et al, 1982a). The standard PC-RPLND became resection of all macroscopic disease

along with a full bilateral infrahilar dissection. This approach provides excellent local control of the retroperitoneum, but is associated with significant morbidity including anejaculation in patients in whom a nerve-sparing technique is not possible.

Several groups investigated whether modified unilateral templates can safely be applied to appropriately selected patients in the postchemotherapy setting (Wood et al, 1992; Herr, 1997; Rabbani et al, 1998; Ehrlich et al, 2006; Beck et al, 2007; Carver et al, 2007a; Steiner et al, 2008; Heidenreich et al, 2009). Table 35-4 lists the results from several studies examining distribution of positive lymph nodes (teratoma and/or viable malignancy) and/or reporting outcomes after selective use of the modified unilateral templates in the postchemotherapy setting. When bilateral dissections were performed, rates of disease outside the unilateral template ranged from 18% to 32% (Carver et al, 2007a). However, rates of disease outside of the unilateral template and outside of macroscopic disease ranged from 2% to 18.6%. Variability in these percentages is likely a function of patient selection and the specific template used. Safe use of the unilateral modified templates in the postchemotherapy setting relies on selection of the correct template as well as appropriate patient selection. **Patients meeting the following criteria may be considered for modified unilateral template PC-RPLND according to data emerging from centers performing these surgeries:**

1. Well-defined lesion measuring 5 cm or less confined to the primary landing zone of the primary tumor on imaging before and after chemotherapy
2. Normal postchemotherapy STMs
3. IGCCCG good/intermediate risk

Figure 35-8 shows representative CT images for candidates for modified unilateral versus bilateral template PC-RPLND. Use of these selection criteria has resulted in in-field retroperitoneal recurrence rates of 0% to 1%, antegrade ejaculation rates of 85% to 94%, and CSS of 98% to 100% at postoperative follow-up times of 2.6 to 7.8 years (Beck et al, 2007; Steiner et al, 2008; Heidenreich et al, 2009). Although these data are encouraging with regard to the use of the modified unilateral templates in PC-RPLND, the standard of care for patients requiring postchemotherapy resection remains resection of all macroscopic disease and a full bilateral infrahilar template RPLND. To date, there have been no prospective studies comparing outcomes in patients undergoing bilateral versus modified unilateral template PC-RPLND. If unilateral modified templates are to be used at PC-RPLND, strict adherence to the above-listed selection criteria is important.

Adjuvant Chemotherapy for Pathologic Stage II Disease at Primary Retroperitoneal Lymph Node Dissection

Primary RPLND alone is curative in approximately 70% of patients with pN1-2 disease, and nearly all patients who experience recurrence are successfully salvaged at the time of recurrence (Donohue et al, 1993a, 1995; Nicolai et al, 2004; Stephenson et al, 2005). Evaluation of two cycles of adjuvant cisplatin-based

chemotherapeutic regimens has consistently demonstrated near-complete elimination of post-RPLND recurrences (Williams et al, 1987; Behnia et al, 2000; Kondagunta et al, 2004). However, pro forma use of adjuvant chemotherapy for pN+ patients would result in overtreatment of approximately 70% of patients without any change in OS. Conversely, treating patients with pN1 and pN2 disease in the adjuvant rather than salvage setting spares patients with recurrent disease full-induction chemotherapy (in most cases one additional cycle of bleomycin, etoposide, Platinol or two additional cycles of etoposide, Platinol). Investigators have attempted to determine which PS II patients are most likely to experience recurrence after primary RPLND.

Although the bulk of retroperitoneal disease encountered at primary RPLND has traditionally been viewed as a predictor of disease recurrence in the absence of adjuvant chemotherapy, this predictive value has not been consistently demonstrated when examining outcomes in patients with PS IIA and IIB disease. Most data demonstrating a direct relationship between retroperitoneal tumor burden and relapse come from early reports in which microscopic disease was separated out from low-volume macroscopic disease (both of which are now grouped together in PS IIA) (Vugrin et al, 1981; Fraley et al, 1985). When evaluating recurrences in the observation arm of a prospective randomized multi-institutional trial evaluating adjuvant cisplatin-based chemotherapy, Williams and coworkers (1987) reported recurrence rates of 40% for patients with microscopically positive nodes, 53% for patients with macroscopic nodal disease smaller than 2 cm, and 60% for patients with disease larger than 2 cm. However, this numeric trend did not reach statistical significance. Several retrospective studies reported no difference in recurrence rates when comparing PS IIA and IIB patients managed with postoperative observation (Pizzocaro and Monfardini, 1984; Donohue et al, 1993b; Nicolai et al, 2010; Al-Ahmadie et al, 2013). In two reports on patients with CS II NSGCT managed with primary RPLND, larger retroperitoneal tumor bulk was associated with increased recurrence rates (Donohue et al, 1995; Weissbach et al, 2000). It is unclear from these retrospective series what selection factors were used to determine which PS II patients were given adjuvant chemotherapy.

Additional histologic characteristics such as number and proportion of positive lymph nodes removed (Beck et al, 2005a; Al-Ahmadie et al, 2013), histology of viable GCT (Beck et al, 2005a; Al-Ahmadie et al, 2013), and extranodal extension (Beck et al, 2007; Al-Ahmadie et al, 2013) have failed to predict reliably patients who are more likely to experience recurrence when managed on post-RPLND surveillance. Patients with PS II disease demonstrating teratoma only in the retroperitoneal specimen demonstrate very low recurrence rates. Given this finding and the chemoresistance of teratoma, adjuvant chemotherapy is not recommended in these patients.

There is general agreement that compliant patients with pN1 disease can be safely observed after RPLND. The management of patients with pN2 disease is controversial. Some investigators recommend two cycles of adjuvant chemotherapy in these patients (Kondagunta and Motzer, 2007). The practice at Indiana University

KEY POINTS: SURGICAL DECISION MAKING

- Patients experiencing a clinical CR to induction chemotherapy generally should be observed. There is some debate regarding the benefit of PC-RPLND in these patients because of the potential for microscopic residual disease.
- The predictable lymphatic spread of testicular GCT has allowed for the establishment of the modified templates for use in patients with low-stage disease.
- The standard of care for PC-RPLND in patients with residual masses includes resection of all macroscopic residual disease and a full bilateral infrahilar template dissection. When modified unilateral templates are used in this setting, strict adherence to the above-outlined criteria is necessary to ensure proper patient selection.
- Administering two cycles of adjuvant cisplatin-based chemotherapy to patients with PS II disease demonstrating viable GCT nearly eliminates postoperative recurrences without affecting OS.

is to offer postoperative surveillance to patients with pN2 disease at primary RPLND.

HISTOLOGIC FINDINGS AT POSTCHEMOTHERAPY RETROPERITONEAL LYMPH NODE DISSECTION AND SURVIVAL OUTCOMES

The report from Indiana in 1982 on postcisplatin cytoreductive surgery was important in that it established the three major histologic categories encountered at PC-RPLND ([Donohue et al, 1982a](#)). In that report, teratoma, fibrosis, and viable GCT were encountered in roughly equal proportions. Since that time, refinement in primary chemotherapeutic regimens and clearer indications for resection have resulted in a decreasing number of patients demonstrating viable malignancy at PC-RPLND. The relative frequencies of fibrosis, teratoma, and viable GCT reported in more contemporary series have generally been 40%, 45%, and 15% ([Steyerberg et al, 1995](#); [Donohue et al, 1998](#); [Hendry et al, 2002](#); [Albers et al, 2004](#); [Carver et al, 2006](#); [Spiess et al, 2007](#)).

Figure 35-8. Computed tomography images of postchemotherapy residual retroperitoneal masses. A, This patient could be considered a candidate for modified right template postchemotherapy retroperitoneal lymph node dissection (PC-RPLND). B, This patient could be considered a candidate for modified left template PC-RPLND. C, This patient would require an extensive bilateral PC-RPLND.

Outcomes by Histology

Fibrosis, teratoma, and viable malignancy are associated with distinct survival outcomes when encountered at PC-RPLND. Survival outcomes as reported in the literature can be found in [Table 35-5](#). The variability of figures within each histologic group is a function of era of treatment, level of pretreatment, study inclusion criteria, and length of follow-up.

Fibrosis/Necrosis

The finding of fibrosis/necrosis only at postchemotherapy resection is associated with favorable RFS and CSS because it indicates a total malignant cell kill in most patients. It can be inferred that the retroperitoneal metastatic deposits harbored no chemoresistant germ cell elements and that any other subclinical metastatic deposits were likely cleared by chemotherapy. CSS and RFS can be expected to approach 95% in these patients ([Donohue and Foster, 1994](#); [Carver et al, 2007c](#); [Maroni et al, 2008](#)).

Teratoma

In 1986, Loehrer and colleagues published the first report dedicated to examining outcomes in patients found to have teratoma only at PC-RPLND. With RFS of 61% and CSS of 82.3%, this series reported poorer outcomes than would be seen in later studies. According to more contemporary outcomes, patients demonstrating teratoma only at PC-RPLND can be expected to demonstrate 80% to 90% RFS and 85% to 95% CSS ([Jansen et al, 1991](#); [Donohue and Foster, 1994](#); [Carver et al, 2006](#)). Investigators found larger mass size after chemotherapy, presence of somatic-type malignancy, and mediastinal primaries to be associated with increased risk of recurrence ([Loehrer et al, 1986](#); [Jansen et al, 1991](#); [Carver et al, 2007b](#)). However, even in the setting of massive retroperitoneal teratoma (>10 cm), 98% CSS has been reported ([Beck et al, 2009](#)).

Viable Malignancy

Persistent viable malignancy encountered at PC-RPLND is associated with a poorer prognosis than teratoma or fibrosis. Reported long-term survival in this group typically ranges from 50% to 70% ([Jansen et al, 1991](#); [Donohue et al, 1998](#); [Fizazi et al, 2001](#); [Spiess et al, 2007](#); [Kundu et al, 2010](#)).

In a multi-institutional review of 238 patients with viable malignancy at PC-RPLND, [Fizazi and associates \(2001\)](#) determined three factors associated with poorer prognosis: (1) incomplete resection, (2) 10% or greater viable malignancy, and (3) IGCCCG intermediate/poor risk stratification at initial diagnosis. Patients with none of these risk factors were classified as “favorable” and demonstrated a 90% 5-year progression-free survival (PFS) and 100% 5-year OS. Patients with one risk factor were classified as “intermediate risk” (5-year PFS 76%, 5-year OS 83%), and patients with two or more risk factors were classified as “poor risk” (5-year PFS 38%, 5-year OS 51%). In a review of 41 patients treated at M.D. Anderson Cancer Center who were found to have viable GCT at PC-RPLND, larger tumor dimension and IGCCCG intermediate/poor risk were associated with increased recurrence rate, whereas persistently elevated α -fetoprotein and prior receipt of salvage chemotherapy were associated with poorer CSS ([Spiess et al, 2007](#)).

Adjuvant Chemotherapy

Adjuvant chemotherapy for viable malignancy at PC-RPLND has never been evaluated in a prospective randomized controlled trial. However, early experience revealed a very poor prognosis when these patients were observed postoperatively ([Einhorn et al, 1981](#)). It was recommended that patients demonstrating viable GCT at PC-RPLND receive postoperative adjuvant cisplatin-based chemotherapy. Although the specific regimen has varied, the number of courses administered in the adjuvant setting after PC-RPLND has generally been two.

*All patients received salvage chemotherapy before postchemotherapy retroperitoneal lymph node dissection.
CSS, cancer-specific survival; NR, not reported; RFS, recurrence-free survival.

Fizazi and colleagues (2001) found that adjuvant chemotherapy was associated with statistically superior PFS without statistical improvement in OS. When dividing patients into the aforementioned viable GCT risk categories, only patients in the intermediate-risk group demonstrated statistically significant improvements in 5-year PFS and OS. Adjuvant chemotherapy seemed to be unnecessary in favorable-risk patients and ineffective in poor-risk patients. In the absence of randomization, these outcomes were likely heavily influenced by selection bias. Similarly, when evaluating patients with viable GCT after salvage RPLND, patients did not appear to benefit from two postoperative cycles of cisplatin-based chemotherapy (Fox et al, 1993; Kundu et al, 2010). Adjuvant chemotherapy is generally not recommended in this setting.

KEY POINTS: HISTOLOGIC FINDINGS AT POSTCHEMOTHERAPY RETROPERITONEAL LYMPH NODE DISSECTION AND OUTCOMES

- Approximately 90% long-term survival can be expected among patients with fibrosis and/or teratoma only at PC-RPLND. This number decreases to 50% to 70% for patients demonstrating viable GCT at PC-RPLND.
- Two cycles of adjuvant chemotherapy are generally recommended in patients with viable GCT at PC-RPLND after induction chemotherapy.

POSTCHEMOTHERAPY RETROPERITONEAL LYMPH NODE DISSECTION IN HIGH-RISK POPULATIONS

Salvage Retroperitoneal Lymph Node Dissection

Patients undergoing PC-RPLND after salvage chemotherapy demonstrated higher rates of persistent viable malignancy and worsened survival outcomes compared with patients who received first-line chemotherapy only (see Table 35-5). Typically, OS and CSS ranged from 60% to 75% in this group (Fox et al, 1993; Donohue et al, 1998; Eggener et al, 2007a). When comparing only patients found to have viable malignancy at PC-RPLND, Fox and associates (1993) reported CSS of 58.5% in patients having received induction chemotherapy only versus 36.7% in patients having received salvage chemotherapy.

Reported experience with RPLND after high-dose chemotherapy (HDCT) is limited (Table 35-6). In 2004, Rick and colleagues reported results in 57 patients undergoing PC-RPLND after HDCT. They observed 59% RFS and 65% CSS at a median follow-up of 7.3 years. Similarly, Cary et al (2011) reported 71% OS at a median follow-up of 4.2 years in 77 patients undergoing RPLND after HDCT.

Desperation Retroperitoneal Lymph Node Dissection

In general, patients with elevated STMs after chemotherapy are not considered candidates for RPLND and are given standard or high-dose salvage chemotherapy. However, a surgical cure remains

possible in selected cases in which chemotherapy has failed to normalize STMs. **Desperation RPLND is resection performed in the setting of elevated STMs.** Pathologic findings at desperation RPLND are listed in Table 35-6. In a review of 114 selected patients undergoing desperation RPLND, Beck and colleagues (2005c) reported a 5-year OS of 53.9% at a median follow-up of 6 years. OS was poorest in patients with viable malignancy demonstrated in the resection specimen, patients who had previously received salvage chemotherapy, patients with increased human chorionic gonadotropin before surgery, or patients who underwent repeat RPLND. Patients who received first-line chemotherapy only and demonstrated declining (but not normalizing) STMs were most likely (>75%) to demonstrate fibrosis and/or teratoma at RPLND. Further chemotherapy would not likely have benefited most of these patients. The authors recommended use of the following selection criteria for desperation RPLND: declining or plateauing STMs after chemotherapy, slowly rising STMs after initial clinical CR to chemotherapy, resectable disease at one or two sites, and as a last resort in a patient with resectable disease and rising STMs after exhausting all reasonable chemotherapeutic options. In a subsequent report on 48 patients by Ong and colleagues (2008), patients with fibrosis at PC-RPLND demonstrated poorer OS than patients with viable malignancy or teratoma likely indicating systemic metastases outside of the retroperitoneum. Patients with postoperative normalization of STMs demonstrated significantly improved OS. This finding was the only prognostic factor that remained robust to multivariable analysis. Outcomes reported in several retrospective desperation series are listed in Table 35-6 (Donohue et al, 1998; Ravi et al, 1998; Albers et al, 2000).

Reoperative Retroperitoneal Lymph Node Dissection

Repeat resection of retroperitoneal recurrence after primary or PC-RPLND has been termed *reoperative* or *redo* RPLND. CSS has been reported to range from 55% to 65% (Donohue et al, 1998; McKiernan et al, 2003; Sexton et al, 2003; Heidenreich et al, 2005; Willis et al, 2007). The reported histologic findings and survival outcomes in reoperative series are listed in Table 35-6. There appears to be a high incidence of GCT with somatic-type malignancy in this population, with a reported incidence of 15% to 20%. Given the technical difficulty of reoperative resections, complications have been reported to occur in approximately one third of patients (McKiernan et al, 2003; Pedrosa et al, 2014). Poorer survival outcomes have been reported in patients demonstrating viable GCT at reoperative RPLND and patients with prior receipt of salvage chemotherapy (McKiernan et al, 2003; Pedrosa et al, 2014).

In most cases, the need for reoperative RPLND likely represents an inadequate primary resection. Several reported findings support this idea. Most patients experience recurrence within the primary landing zone (McKiernan et al, 2003; Heidenreich et al, 2005). Pedrosa and colleagues (2014) reported that ipsilateral recurrence was associated with incomplete ipsilateral lumbar vessel ligation and an unresected ipsilateral gonadal vein. Similarly, Willis and colleagues (2007) reported that 46% of reoperative cases demonstrated retroaortic and/or retrocaval disease, indicating that these regions were omitted from prior RPLND. Using good technique at initial RPLND decreases the likelihood of having to perform a reoperative RPLND.

Late Relapse

Late relapse is defined as recurrence of GCT 24 or more months after CR to primary treatment modalities. This is a rare phenomenon that occurs in 2% to 4% of patients with GCT (Baniel et al, 1995a; Gerl et al, 1997). The retroperitoneum is the most common site of late relapse (Baniel et al, 1995a). Approximately 80% of cases of late relapse contain viable GCT with yolk sac tumor predominating (Baniel et al, 1995a; Michael et al, 2000; George et al, 2003; Sharp et al, 2008). Additionally, there appears to be a disproportionately high incidence of GCT with somatic-type malignancy. When late relapse occurs in patients who previously received

chemotherapy, it is rarely cured by chemotherapy. **Surgical extirpation should be the initial management of all patients with resectable disease at late relapse.** Patients with widespread and/or unresectable disease should be offered chemotherapy in an effort to downsize the tumor burden and render the disease resectable. Reported OS is usually around 60%. Predictors of poorer survival outcomes include viable malignancy or somatic-type malignancy at late relapse, prior chemotherapy, and incomplete resection (Baniel et al, 1995a; George et al, 2003; Sharp et al, 2008).

KEY POINTS: POSTCHEMOTHERAPY RETROPERITONEAL LYMPH NODE DISSECTION IN HIGH-RISK POPULATIONS

- PC-RPLND performed as a salvage, desperation, or reoperative procedure or in the setting of late relapse is associated with significantly poorer survival outcomes than PC-RPLND performed after complete serologic response to induction chemotherapy.
- Viable GCT is encountered in an increased proportion of patients within all of these subpopulations. Additionally, somatic-type malignancy is seen with increased frequency in patients undergoing reoperative RPLND and patients undergoing resection of late relapse disease.
- In general, patients with elevated STMs after induction chemotherapy should receive salvage chemotherapy. Only patients satisfying the above-outlined selection criteria should be considered for desperation RPLND.
- Reoperative RPLND generally indicates an inadequate prior RPLND. Increased complication rates and poorer survival outcomes in this setting highlight the importance of proper surgical technique at initial RPLND.
- Late relapse in patients who previously received chemotherapy is generally chemoresistant. First-line management of late relapse in all patients with resectable disease should be surgical extirpation.

SURGICAL OUTCOMES, FUNCTIONAL CONSIDERATIONS, AND COMPLICATIONS OF RETROPERITONEAL LYMPH NODE DISSECTION

Lymph Node Counts

Higher lymph node counts have been associated with improved oncologic outcomes in various malignancies (Herr et al, 2002; Le Voyer et al, 2003; Schwarz and Smith, 2006, 2007). Given these findings, some investigators have proposed that node counts be used as surrogates for adequacy of lymphadenectomy. In recent years, several groups have investigated lymph node counts in primary and PC-RPLND (Carver et al, 2010; Risk et al, 2010; Thompson et al, 2010, 2011). Although investigators at MSKCC reported a direct correlation between node count and node positivity when evaluating patients with primary RPLND (Thompson et al, 2010), no such association was appreciated in two other studies (Lieberman et al, 2010; Risk et al, 2010). Significant variability in lymph node counts, demonstrated by wide interquartile range and large standard deviation, indicates that node counts are not useful when assessing adequacy of an individual surgery (Risk et al, 2010; Thompson et al, 2010). However, surgeons and treatment centers may consider reviewing their own mean or median lymph node counts to determine if their numbers reflect those reported in the literature for the templates used. If lymph node counts are consistently lower than published standards, there may be a problem related to thoroughness of surgery and/or pathologic processing of specimens obtained.

Retroperitoneal Lymph Node Dissection and Fertility

Fertility in Patients Undergoing Retroperitoneal Lymph Node Dissection

Preserving fertility in men undergoing RPLND is more complex than simply sparing their postganglionic sympathetic nerves. Subfertility in a significant proportion of patients presenting with newly diagnosed testicular cancer is well documented. When including all stages of disease, approximately 40% to 60% of patients presenting with testicular GCT have been reported to demonstrate abnormal parameters on semen analysis (Fossa et al, 1985; Lange et al, 1987; Hansen et al, 1991; Foster et al, 1994). Baseline subfertility needs to be taken into account when evaluating paternity rates after RPLND.

Ejaculatory Dysfunction and Retroperitoneal Lymph Node Dissection

For successful antegrade ejaculation of sperm-containing semen to occur, several processes need to occur in coordinated fashion, as follows: (1) smooth muscle contraction in the vasa deferentia, seminal vesicles, and prostate resulting in seminal emission and prostate glandular secretion along with (2) closure of the bladder neck to prevent retrograde ejaculation and (3) rhythmic contractions of the ischiocavernosus, bulbospongiosus, and levator ani muscles expelling semen from the urethra. Processes 1 and 2 require efferent neurologic input from the L1 through L4 postganglionic sympathetic fibers, which coalesce with their contralateral counterparts in the superior hypogastric plexus. From the hypogastric plexus, these nerve fibers continue caudally to the seminal vesicles, ampulla of the vasa deferentia, vasa deferentia proper, bladder neck, and prostate (Donohue et al, 1990).

Before the development of unilateral modified RPLND templates and nerve-sparing techniques, most patients undergoing bilateral RPLND were rendered anejaculatory (Donohue and Rowland, 1981). In light of the successful nerve preservation techniques established for radical retropubic prostatectomy by Walsh and Donker (1982), testicular cancer surgeons sought to refine the surgical technique of RPLND with the goal of preserving antegrade ejaculation without compromising diagnostic and therapeutic efficacy. Techniques were altered in two ways: (1) changing the boundaries of dissection (Pizzocaro et al, 1985; Weissbach et al, 1985) and (2) prospectively identifying postganglionic sympathetic fibers and the superior hypogastric plexus so that these structures could be preserved during subsequent lymphadenectomy (Jewett et al, 1988).

Early studies on ejaculatory outcomes after modified unilateral template RPLND without nerve-sparing technique reported postoperative antegrade ejaculation in 75% to 87% of patients (Fossa et al, 1985; Pizzocaro et al, 1985; Weissbach et al, 1985). However, in a more recent series, Beck and colleagues (2010) reported preservation of antegrade ejaculation in 97% of men undergoing modified unilateral template dissection without ipsilateral nerve-sparing technique. These superior outcomes likely reflect improved understanding of the anatomy of postganglionic sympathetic nerve fibers allowing for the avoidance of damage to contralateral fibers caudal to the IMA.

Nerve-sparing RPLND results in preservation of antegrade ejaculation in 90% to 100% of patients (Jewett and Torbey, 1988; Donohue et al, 1990; Heidenreich et al, 2003; Beck et al, 2010). Although Jewett and Torbey (1988) reported temporary postoperative anejaculation in most patients, Donohue (1993) observed no such anejaculatory period. In the study by Jewett and Torbey (1988), bilateral template RPLND was performed in all patients, whereas ipsilateral nerve-sparing and modified unilateral template dissections were performed in most patients in the study by Donohue (1993). Neurapraxia likely accounted for the temporary anejaculation reported by Jewett and Torbey (1988).

In addition to demonstrating the efficacy of unilateral template dissection and nerve-sparing techniques in preserving antegrade ejaculation, these studies provided evidence that these new techniques did not compromise oncologic outcomes. With follow-up ranging from 10 months to nearly 5 years, only one retroperitoneal recurrence was reported in the aforementioned series. However, heterogeneous indications for use of post-RPLND adjuvant chemotherapy almost certainly affected recurrence rates.

Over the last 30 years, refinements in the technique of primary RPLND and PC-RPLND have resulted in a significant decrease in the incidence of postoperative ejaculatory dysfunction. Through the use of modified unilateral dissection templates and/or nerve-sparing techniques, preservation of antegrade ejaculation can be expected in greater than 90% of patients in whom at least one of these modalities can be employed. Postoperative paternity can be expected in approximately 75% of men undergoing primary nerve-sparing RPLND (Beck et al, 2010). Fertility after PC-RPLND has not been established because chemotherapy-induced disruption of spermatogenesis can persist for several years after completion of therapy (Lampe et al, 1997).

Complications of Retroperitoneal Lymph Node Dissection

The overall complication rate for primary RPLND has been reported to range from 10.6% to 24% (Baniel et al, 1994; Heidenreich et al, 2003; Subramanian et al, 2010). Reported complication rates for PC-RPLND range from 20% to 30% (Baniel et al, 1995b; Subramanian et al, 2010). Given the paucity of studies on this topic, predictors of complications after RPLND have been inconsistent. When evaluating primary RPLND, investigators at Indiana University reported lower complication rates associated with unilateral dissection and more recent era of surgery. The German Testicular Cancer Study Group found no such correlation between RPLND template and complications. However, investigators reported increased complication rates when RPLND was performed by surgeons with a lower volume of cases and/or at lower volume centers, leading to a recommendation to centralize RPLND to high-volume centers and to minimize the number of surgeons performing these surgeries at each center.

Table 35-7 summarizes reported complications in primary RPLND and PC-RPLND. A review of the incidence, prevention, and management of select complications follows.

Pulmonary Complications

Major pulmonary complications are extremely rare after primary RPLND but have been reported to occur in approximately 3% to 5% of patients after PC-RPLND (Baniel et al, 1994, 1995b; Heidenreich et al, 2003; Subramanian et al, 2010). Because most patients who undergo PC-RPLND have received bleomycin-containing induction chemotherapy, acute respiratory distress syndrome and prolonged postoperative ventilation account for most of these major complications. The incidence of bleomycin-related perioperative pulmonary complications can be minimized by avoiding aggressive intraoperative and postoperative intravenous fluid resuscitation and keeping FiO_2 as low as is safely possible (Goldiner et al, 1978; Donat and Levy, 1998). The importance of working with an anesthesiologist who has experience in managing patients who previously received bleomycin cannot be overstated. Pulmonary complications are most likely to be encountered in patients with large-volume pulmonary disease, particularly if simultaneous retroperitoneal and thoracic resections are to be performed (Baniel et al, 1995b).

Ileus

The reported rates of postoperative paralytic ileus range widely in the primary RPLND (0% to 18%) and PC-RPLND (2.2% to 21%) settings. This variation likely stems from differences in the definitions of ileus. In relatively low-volume PC-RPLND, an orogastric tube is used and removed at the conclusion of the procedure. In

higher volume disease, the probability of significant ileus is greater, and a nasogastric tube should be used.

Lymphocele

The incidence of subclinical lymphocele after RPLND is unknown. However, it is thought that lymphoceles are relatively common and clinically insignificant in most cases. Symptomatic retroperitoneal lymphoceles are extremely rare with reported rates ranging from 0% to 1.7% (Baniel et al, 1994, 1995b; Heidenreich et al, 2003; Subramanian et al, 2010). Symptoms can be related to ureteral compression, displacement of abdominal viscera (if very large), or secondary infection. CT scan demonstrates a thin-walled cystic lesion in the resection bed. Air within the lymphocele and/or rim enhancement should raise concern for an infection. **Meticulous attention to ligation of large-caliber lymphatics during resection likely decreases the risk of developing a symptomatic lymphocele.** Treatment of symptomatic and/or infected lymphoceles includes percutaneous drainage with systemic antibiotics reserved for infected lymphoceles. Additionally, in the setting of infected lymphocele, one should consider leaving an indwelling drain rather than simple percutaneous aspiration.

Chylous Ascites

Chylous ascites refers to the accumulation of chylomicron-containing lymphatic fluid in the peritoneal cavity. **Chylous ascites has been reported to occur in 0.2% to 2.1% of patients undergoing primary RPLND and 2% to 7% of patients undergoing PC-RPLND** (Baniel et al, 1994, 1995b; Heidenreich et al, 2003; Evans et al, 2006; Subramanian et al, 2010). Patients typically present with complaints of increasing abdominal fullness, anorexia, nausea, vomiting, abdominal pain, and dyspnea. Patients often have a fluid wave on abdominal examination, which can help distinguish ascites from an ileus. Additionally, accumulated peritoneal fluid results in significant weight gain. Fluid has a milky color if paracentesis is performed. Chylous ascites is alkaline, stains positive for Sudan black, and demonstrates a triglyceride concentration greater than that of serum. However, these tests are usually unnecessary because clinical examination and/or gross inspection of aspirating fluid should be enough to confirm the diagnosis.

Suprahilar resections are thought to carry a higher risk for chylous ascites because of disruption of the cisterna chyli and

its contributing lymphatics. The cisterna chyli is located at the level of the L1-2 vertebral bodies, medial to the posterior surface of the aorta in the retrocrural space. The association of IVC resection and chylous ascites is thought to be related to increased venous pressure below the level of the IVC producing increased capillary leak and ultimately third spacing of lymphatic fluid into the retroperitoneum (Baniel et al, 1993). In a review of the M.D. Anderson Cancer Center experience, Evans and colleagues (2006) found increased number of preoperative cycles of chemotherapy, increased estimated blood loss, and longer operative time to be associated with development of chylous ascites.

We recommend a graduated approach to the management of chylous ascites. In general, patients with symptomatic chylous ascites should first be managed with paracentesis. Although an indwelling drain can be left, we recommend simple paracentesis with consideration of low-fat/medium-chain triglyceride diet and intramuscular octreotide. If ascites reaccumulates, an indwelling drain should be placed. If these dietary modifications have already been instituted, patients should be given nothing by mouth, and total parenteral nutrition should be initiated. Although the use of octreotide in the setting of chylous ascites has not been studied in the urologic literature, it has demonstrated efficacy in minimizing chylous leaks after hepaticopancreaticobiliary surgery (Shapiro et al, 1996; Kuboki et al, 2013). Persistent high-volume chylous drainage (>100 mL/24 hr) despite these modifications is exceedingly rare. When it does occur, options include continued observation with conservative management, placement of a peritoneovenous (LeVeen) shunt, or surgical exploration with attempted ligation of the lymphatic leak. The latter two options should be reserved as last resorts. Peritoneovenous shunts have been reported to be associated with a significant incidence of occlusion and/or malfunction often requiring revision after placement, sepsis, and potentially fat embolization (Evans et al, 2006). Regardless of treatment modality that ultimately results in resolution of chylous ascites, consideration should be given to a continued low-fat diet with medium-chain triglycerides for 1 to 3 months after resolution of lymph leak.

Venous Thromboembolism

Venous thromboembolism (VTE) rates reported after primary RPLND and PC-RPLND are consistently low; this is likely the result

of a young, otherwise healthy patient population. The rate of pulmonary embolism after primary RPLND has been reported to be less than 1% (Baniel et al, 1994; Heidenreich et al, 2003; Subramanian et al, 2010). After PC-RPLND, the rates range from 0.1% to 3.1% (Baniel et al, 1995b; Subramanian et al, 2010). The incidence of deep venous thrombosis is more difficult to determine because these cases are not consistently reported in the literature and are likely most often asymptomatic. Reported rates range from 0% to 1% in primary RPLND and PC-RPLND (Heidenreich et al, 2003; Subramanian et al, 2010).

All patients undergoing RPLND should have sequential compression devices placed before induction, which should be maintained throughout the hospital course. Ambulation should be resumed on postoperative day 1 in virtually all cases. The use of pharmacologic prophylaxis has never been evaluated in patients undergoing RPLND. Prophylactic subcutaneous low-dose unfractionated heparin or low-molecular-weight heparin has demonstrated efficacy in decreasing VTE rates in postoperative patients (Collins et al, 1988; Kakkar et al, 1993). The potential disadvantages are an increased risk for postoperative hemorrhage and anecdotal reports of increased risk for lymphocele. Retrospective studies on patients undergoing radical prostatectomy reported conflicting results with regard to the effect of postoperative pharmacologic thromboprophylaxis on pelvic lymphocele formation (Bigg and Catalona, 1992; Koch and Jr, 1997; Schmitges et al, 2012). The decision to use pharmacologic thromboprophylaxis needs to be made based on the low incidence of VTE in patients undergoing RPLND and extrapolation of data based on risk/benefit data from other surgeries and specialties. Pharmacologic thromboprophylaxis is likely most important in patients who are at an increased risk for postoperative VTE, such as patients with a personal history of VTE, obesity, known hypercoagulable condition, or older age.

Neurologic Complications

In the Indiana PC-RPLND review, no cases of paraplegia were noted. Seven cases of peripheral nerve injury were reported (Baniel et al, 1995b). All of these cases were secondary to patient positioning and potentially retractor placement (femoral neurapraxia). Careful attention to appropriate patient positioning by the surgical and anesthesia teams is important in minimizing peripheral nerve damage. In a review of 268 patients undergoing postchemotherapy resection of mediastinal disease for testicular or primary retroperitoneal GCT, Kesler and colleagues (2003) reported 6 patients (2.2%) with paraplegia. Patients with bulky mediastinal and retroperitoneal disease are at an increased risk of developing paraplegia. The likelihood of neurologic complications increases with the scale of para-aortic resection.

Mortality

Reported mortality after primary RPLND is essentially zero (Baniel et al, 1994; Heidenreich et al, 2003; Capitanio et al, 2009; Subramanian et al, 2010). Mortality after PC-RPLND is extremely rare and generally reported to be less than 1% (Baniel et al, 1995b; Capitanio et al, 2009; Subramanian et al, 2010). In a review of the Indiana University experience, 5 of 603 patients (0.8%) died after PC-RPLND (Baniel et al, 1995b). Causes of death were severe respiratory distress in two patients, multiple organ failure in one patient, fungal sepsis in one patient, and myocardial infarction after aorticoduodenal fistula in one patient. In a population-based study of 882 patients having undergone RPLND, Capitanio and colleagues (2009) used the Surveillance, Epidemiology, and End Results (SEER) database to determine if mortality rates previously reported by centers of excellence were applicable to the community. Although receipt of chemotherapy was not reported, there were no mortalities among patients with localized disease, whereas mortality rates of 0.8% and 6% were reported among patients with retroperitoneal disease and distant metastases, respectively.

KEY POINTS: SURGICAL OUTCOMES, FUNCTIONAL CONSIDERATIONS, AND COMPLICATIONS OF RETROPERITONEAL LYMPH NODE DISSECTION

- Through the use of modified unilateral templates and nerve-sparing techniques, preservation of antegrade ejaculation can be expected in nearly all patients undergoing primary RPLND. Similar success rates are possible in patients undergoing PC-RPLND when one or both of these techniques can be safely performed. However, this is often impossible in patients with large retroperitoneal masses.
- Major complications are rare after primary RPLND and PC-RPLND. A significant proportion of major complications at PC-RPLND are pulmonary and are related to prior bleomycin and thoracic disease burden. Anesthesia providers play a key role in minimizing these events.
- Although very rare, chylous ascites can be a challenging complication to manage. Careful attention to retroperitoneal lymphatic anatomy with ligation of large-caliber lymphatics is thought to minimize the risk of this complication.
- A graduated approach to the management of chylous ascites is recommended.
- Paraplegia after RPLND is vanishingly rare. However, patients undergoing resection of large-volume retroperitoneal and visceral mediastinal disease should be counseled regarding the potential for this devastating complication.

RETROPERITONEAL LYMPH NODE DISSECTION IN UNIQUE SITUATIONS

Postchemotherapy Retroperitoneal Lymph Node Dissection for Seminoma

Pure seminoma is a particularly chemosensitive tumor with CR rates of 70% to 90% being reported in patients with disseminated disease treated with cisplatin-based chemotherapy (Loehrer et al, 1987; International Germ Cell Consensus Classification, 1997; Gholam et al, 2003). Residual masses are relatively common after treatment of seminoma owing to the intense desmoplastic reaction occurring in response to chemotherapy. In most series of PC-RPLND performed for pure seminoma, viable malignancy is encountered in approximately 10% of cases, with remaining patients demonstrating only fibrosis (Herr et al, 1997; Ravi et al, 1999; Flechon et al, 2002). Additionally, PC-RPLND for seminoma has been associated with increased perioperative morbidity compared with PC-RPLND for NSGCT (Friedman et al, 1985; Fossa et al, 1987; Mosharafa et al, 2003b). Various thresholds for operative intervention have been derived with the common goal of avoiding an often unnecessary and potentially morbid surgery.

In a review of 55 patients treated at MSKCC with pure testicular seminoma and available postchemotherapy retroperitoneal pathology (RPLND or biopsy), 30% of patients with masses 3 cm or larger had viable retroperitoneal seminoma or teratoma at resection, whereas none of the patients with smaller masses harbored residual disease (Herr et al, 1997). Investigators recommended RPLND in patients with pure seminoma with residual masses 3 cm or larger. Conversely, investigators at Indiana University reported no association between residual mass size and disease recurrence/progression on observation in their experience with 21 patients. The authors recommended observing all residual masses with resection reserved for patients demonstrating serologic or radiographic evidence of progression (Schultz et al, 1989).

More recently, PET has been used to assess for the presence of viable seminoma in residual masses. In this capacity, PET scans have a negative predictive value approaching 100%. However, false-positive PET scans have resulted in inconsistent positive predictive values ranging from 67% to 100% in two studies (De Santis et al,

2004; Lewis et al, 2006). In light of these findings, some guidelines propose that patients without residual masses or a residual mass less than 3 cm be observed and patients with larger masses be evaluated with a PET scan 6 weeks after completing chemotherapy. Patients with PET-avid masses are managed with RPLND, standard-dose salvage chemotherapy, or HDCT. Of these three modalities, HDCT has demonstrated the best survival outcomes with 92% OS when it is used in the second-line setting (Agarwala et al, 2011). In a review of 36 patients with pure seminoma demonstrating viable seminoma at PC-RPLND, Rice and colleagues (2012) reported a 54% CSS with only 9 patients (25%) remaining continuously disease-free after resection. Given the superior survival outcomes associated with HDCT, this modality is preferred for most patients with pure seminoma who relapse after induction chemotherapy. However, PC-RPLND may continue to have a role for management of patients who relapse with focal, easily resectable masses to avoid the potential morbidity of HDCT. Ultimately, the decision needs to be made based on predicted morbidity of resection versus HDCT.

Retroperitoneal Lymph Node Dissection for Sex Cord–Stromal Tumors

Sex cord–stromal tumors (SCSTs) account for 4% to 5% of all testicular neoplasms and include Leydig, Sertoli, and granulosa cell tumors as well as various combinations of these histologies. It is estimated that 10% to 20% of adult SCSTs are malignant (Kim et al, 1985; Grem et al, 1986; Kratzer et al, 1997). Although the presence of metastatic disease is the only reliable indicator of malignant phenotype, various primary tumor characteristics have been evaluated for their ability to predict aggressive behavior. Features seeming to correlate with aggressive behavior have been fairly similar when examining the distinct subtypes of SCSTs. These characteristics include older age, primary tumor size larger than 4 to 5 cm, necrosis, mitotic rate greater than three to five per 10 high-power fields, moderate-to-severe nuclear atypia, infiltrative tumor margins/invasion of adjuvant structures, and lymphovascular invasion (Kim et al, 1985; Dilworth et al, 1991; Kratzer et al, 1997; Young et al, 1998). Multiple features predictive of malignant phenotype frequently occur in the same patients, with patients demonstrating a malignant disease course often possessing two or three malignant characteristics (Kim et al, 1985; Young et al, 1998). Some experts recommended that tumors possessing two or more such features be categorized as malignant (Kratzer et al, 1997; Silberstein et al, 2013). However, prediction of malignant behavior based on histology is not as accurate as in GCT.

The role of RPLND in the treatment of SCST is unclear. Arguments for use of RPLND in treatment of this disease are as follows: (1) Retroperitoneal nodes are consistently the most common (and likely the first) site of metastases in reported series (Kim et al, 1985; Kratzer et al, 1997; Young et al, 1998); (2) CS I patients can go on to develop retroperitoneal metastases at widely ranging time intervals indicating that early primary RPLND could perhaps prevent these recurrences (Mosharafa et al, 2003a); (3) there have been isolated reported cases of surgically cured patients with microscopic deposits of SCST in RPLND specimens (Lockhart et al, 1976; Gohji et al, 1994; Mosharafa et al, 2003a; Silberstein et al, 2013); and (4) although these tumors have been reported to demonstrate partial responses to chemotherapy, cures have not been documented.

Arguments against performing RPLND are as follows: (1) Primary tumor histologic predictors of malignant behavior have demonstrated inconsistent performance making patient selection difficult (Mosharafa et al, 2003a; Silberstein et al, 2013), and (2) although there have been some surgical cures reported in the literature, follow-up is often too short to confirm cure, and most patients with positive retroperitoneal nodes die of their disease. At the present time, no conclusive recommendation can be made regarding the use of RPLND in managing patients with SCST. The aforementioned advantages and disadvantages should be discussed with

the patient to allow him to make an informed decision regarding management.

KEY POINTS: RETROPERITONEAL LYMPH NODE DISSECTION IN UNIQUE SITUATIONS

- PC-RPLND is rarely performed in the setting of seminoma given the chemosensitivity of this histology, the technical difficulty of these resections, and the excellent response to HDCT.
- The role of RPLND in the treatment of SCST has not been definitively demonstrated given the rarity of malignant forms of these tumors.

CONCLUSION

Over the last 50 years, the field of testicular cancer has undergone a striking evolution through the parallel development and integration of more effective and less toxic chemotherapeutic regimens and the continued refinement of techniques for surgical resection. These advances have resulted in delivery of durable cures to more than 90% of patients with testicular cancer, while minimizing acute and long-term morbidity. These excellent outcomes can be achieved only through strict adherence to established therapeutic principles. Although treatment of patients with testicular cancer often requires an experienced multidisciplinary team, the successful management of nearly every patient with testicular cancer begins with his urologist. All urologists should have a thorough and nuanced understanding of the appropriate treatment of testicular cancer. This understanding helps to ensure expeditious delivery of appropriate medical and surgical treatment with early referral to high-volume centers when necessary. The success of surgical management of testicular tumors is measured not only by survival outcomes but also by minimizing morbidity through avoidance of unnecessary surgeries and functional preservation whenever possible.

Prospective Nerve-Sparing Techniques

Complications

Results and Current Status

Summary

Germ cell tumors (GCTs) are the most common malignancy in men between the ages of 15 and 35 (Carver and Sheinfeld, 2005). Testicular cancer is also one of the most curable solid-organ neoplasms, owing in large part to an excellent multimodal treatment paradigm that includes effective platinum-based chemotherapy and surgery (Einhorn, 1981). **Although contemporary survival rates for GCTs are more than 90%, cure rates and patient morbidity depend on selection of the management options.** Retroperitoneal lymph node dissection (RPLND) plays a major role in the management of patients with GCTs. The role of surgery continues to evolve owing to advances in chemotherapy regimens, clinical staging modalities, and continued surgical innovation (Sheinfeld and Herr, 1998; Allaf et al, 2005; Albers et al, 2008).

Primary chemotherapy is favored in Europe, whereas RPLND traditionally has been the management strategy of choice in the United States for high-risk patients with clinical stage I nonseminomatous germ cell tumor (NSGCT). RPLND can accurately stage the retroperitoneum and positively identify patients harboring metastases. In addition, patients with pathologic stage I disease are spared the toxicity and morbidity of any additional therapy because 90% or more experience long-term disease-free survival with surgery alone. Patients with pathologic stage II disease can learn more about the extent of their disease and make informed decisions regarding further therapy after RPLND. For patients in this group who harbor small-volume retroperitoneal disease (pN1), a properly performed RPLND can be curative in approximately 70% of men, so chemotherapy also can be avoided in this setting (Richie and Kantoff, 1991; Donohue et al, 1993; Rabbani et al, 2001). Because the retroperitoneum is the most frequent site of chemoresistant malignant GCT and teratoma, both of these processes are minimized with RPLND (Baniel et al, 1995). Some groups advocate RPLND as the treatment of choice for all men with clinical stage I NSGCT with teratoma in the orchiectomy specimen given the increased propensity of harboring teratoma in the retroperitoneum (Sheinfeld et al, 2003). RPLND eliminates these chemoresistant elements and maximizes therapeutic efficacy.

Traditionally, RPLND for GCTs has been performed via an open transabdominal or thoracoabdominal approach. Over the past two decades, minimally invasive approaches for the treatment of various malignancies have emerged and become popular. Since the early

1990s, retroperitoneal laparoscopic surgery has been used with proven benefits related to reducing perioperative morbidity, improving cosmesis, and shortening convalescence without compromising oncologic efficacy (Cadeddu et al, 1998; Allaf et al, 2004; Permpongkosol et al, 2005). Laparoscopic RPLND (L-RPLND) and more recently robotic-assisted RPLND (RA-RPLND) are technically demanding procedures that are increasingly being performed by experienced surgeons aiming to minimize morbidity while duplicating the open technique. **Given that untreated retroperitoneal disease and late relapses in the retroperitoneum are fatal and can be chemorefractory, it is of paramount importance that, as in open RPLND, a complete “cleanout” of lymph nodes is performed** (Whitmore, 1979; Borge et al, 1988; Baniel et al, 1995; Carver et al, 2005).

In this chapter, the evolution of L-RPLND and RA-RPLND is summarized. Controversies surrounding their use, surgical techniques, outcomes, and associated complications are discussed. The focus is on the management of low-stage NSGCTs and the role of these minimally invasive approaches after chemotherapy.

RATIONALE AND EVOLUTION

In an effort to decrease the morbidity associated with open RPLND, shortly after the introduction of laparoscopic renal surgery in 1991, several reports emerged documenting the feasibility of L-RPLND in the management of clinical stage I NSGCT (Rukstalis and Chodak, 1992; Stone et al, 1993; Klotz, 1994). Larger retrospective series followed suggesting decreased blood loss, shorter hospital stays, and faster return to normal activity compared with open RPLND, with preservation of antegrade ejaculation in more than 95% of patients (Gerber et al, 1994; Janetschek et al, 1994, 1996). An early multi-institutional retrospective analysis demonstrated preservation of antegrade ejaculation in all patients, short hospital stays (<3 days), and return to normal activity at 2 to 3 weeks postoperatively (Gerber et al, 1994). **The abbreviated convalescence allows patients who are candidates to receive chemotherapy with minimal delay.** These attractive early results encouraged others to investigate L-RPLND as a viable treatment option for low-stage NSGCT.

STAGING LAPAROSCOPIC RETROPERITONEAL LYMPH NODE DISSECTION AND CONTROVERSY

Of all laparoscopic applications to surgical urology, L-RPLND has raised the most controversy. This controversy is due to the technical difficulty of RPLND in general, the limited number of cases, and lack of interest at traditional centers of excellence. Laparoscopy is an access technique with the internal procedure being performed the same as with an open incision. Experience drives an equivalent dissection. In all early series and some contemporary studies, L-RPLND was used as a staging procedure (Bianchi et al, 1998; Janetschek et al, 2000). Patients not harboring occult metastases were identified and spared exposure to chemotherapy without undergoing open RPLND. In this form, L-RPLND was performed without retrocaval or retroaortic dissection, and chemotherapy was given to all patients harboring metastatic disease (including patients with pN1 disease). The decision to omit dissection behind the great vessels was based on the belief of a lack of isolated positive lymph nodes in this area (Holtl et al, 2002). Within this paradigm, the procedure was routinely aborted if positive lymph nodes were encountered, and chemotherapy was instituted in these cases (Bianchi et al, 1998; Nelson et al, 1999). In contemporary series, this approach has been abandoned, and L-RPLND has evolved into a therapeutic procedure duplicating the open approach in its intent (Allaf et al, 2005; Steiner et al, 2008; Hyams et al, 2012).

The use of restrictive template boundaries coupled with the universal use of chemotherapy in men harboring pathologic stage II disease generated criticism of published L-RPLND series. The controversy regarding the use of “staging” L-RPLND hinges on mapping studies demonstrating increased multifocality and contralateral disease in the presence of positive retroperitoneal nodes (Ray et al, 1974; Donohue et al, 1982; Weissbach and Boedefeld, 1987; Eggener et al, 2007). Critics argue that the liberal use of chemotherapy would not prevent relapses and compensate for incomplete resection.

DUPLICATION OF OPEN RETROPERITONEAL LYMPH NODE DISSECTION

At experienced centers at the present time, an exact replication of the open template is performed on all patients with NSGCT undergoing L-RPLND with wide templates and complete excision of retroaortic and retrocaval tissue, rendering the procedure both a staging and a therapeutic operation. Some groups perform a bilateral dissection on all patients, whereas others reserve bilateral dissection for patients with lymph node involvement (Allaf et al, 2005; Steiner et al, 2008).

DEVELOPMENT OF ROBOTIC-ASSISTED RETROPERITONEAL LYMPH NODE DISSECTION

Robotic technology has become ubiquitous within the urologic oncology community, and it is believed to have facilitated a minimally invasive approach to complex urologic operations such as radical prostatectomy and partial nephrectomy. Robotic technology has been shown to increase use of partial nephrectomy, likely owing to perceived ease in facility of this complex laparoscopic procedure (Patel et al, 2013). Given the wide range of robotic procedures performed by urologists and given that L-RPLND requires a complex laparoscopic skill set, small case series of RA-RPLND have emerged demonstrating safety and feasibility (Daval et al, 2006; Williams et al, 2011).

SURGICAL TECHNIQUE

L-RPLND is a technically challenging procedure associated with a steep learning curve and should be undertaken by experienced laparoscopic surgeons who are comfortable and adept with advanced

vascular techniques and open surgery in case of conversion. The indications for primary L-RPLND are identical to the indications for open RPLND and include clinical stage I or IIA disease, negative serum tumor markers, and the absence of comorbidities that would preclude safe surgery. In the postchemotherapeutic setting, L-RPLND has been limited mainly to small-volume residual disease; however, experienced surgeons have excised bulky tumors. **The surgical template for the procedure is dictated by laterality and intraoperative findings. Surgical margins should not be compromised to minimize morbidity, to preserve ejaculation, or because of technical constraints. The extent of the node dissection can be expanded based on intraoperative findings.**

Preoperative Patient Preparation and Technical Considerations

All patients considered candidates for L-RPLND must be fully informed of all treatment options, including open RPLND, chemotherapy, and surveillance. All potential complications including bleeding requiring blood transfusion; injury to adjacent organs (liver, bowel, gallbladder, kidney, ureter, pancreas, major vascular structures); and orthopedic, neurologic, or pulmonary complications as well as conversion to open surgery because of complications or incomplete resection should be discussed (Allaf et al, 2005; Winfield, 1998). Patients interested in future fertility are educated regarding preoperative sperm banking. Some surgeons advocate a low-fat diet 1 to 2 weeks before surgery to reduce the risk of chylous ascites, but data regarding this practice are not definitive. Patients undergo a mechanical bowel preparation the afternoon before surgery and take only clear liquids until midnight to decompress the bowels. Preoperative antibiotics are given before surgery, and antiembolism devices are placed on the lower extremities to minimize deep vein thrombosis.

Standard laparoscopic instruments are used throughout this procedure (e.g., atraumatic graspers, scissors, clip appliers, irrigation/suction device, and laparoscopic paddle retractor). Radiolucent polypropylene clips (Hem-o-lok; Weck Closure Systems, Triangle Park, NC) may minimize artifact on postoperative imaging of the retroperitoneum. In addition, a needle driver loaded with suture and adjunct hemostatic agents such as gelatin matrix (FloSeal Matrix Hemostatic Sealant; Fusion Medical Technologies, Fremont, CA) or oxidized cellulose (Surgicel; Ethicon, Piscataway, NJ) should be readily available in case of vascular injury. Sealing devices such as ultrasonic shears and bipolar devices should be used with caution and can be unreliable in sealing large lymphatic channels. A laparoscopic retractor is particularly useful for medial retraction of the bowel and alleviates the need to position the patient in a modified flank position. A gauze sponge placed in the abdomen can be helpful in tamponading bleeding.

Approach

Although some surgeons use an extraperitoneal approach (Hsu et al, 2003; Hara et al, 2004), most prefer a transperitoneal approach owing to the larger and more familiar working space. **Additionally, a transperitoneal approach facilitates bilateral dissection when warranted by allowing access to all four quadrants.**

Patient Positioning and Port Placement for Laparoscopic Retroperitoneal Lymph Node Dissection

After general anesthesia is induced, an orogastric tube and Foley catheter are inserted. The patient may be placed in the modified flank position (45 degrees) with the side of dissection elevated, but we prefer the supine position because it makes transitioning to a bilateral dissection less cumbersome and does not require patient repositioning (Fig. 36-1). Great care is taken to pad all pressure points to minimize the risk of nerve injury or rhabdomyolysis because these surgeries may require a longer time than their open

Figure 36-1. Patient positioning during laparoscopic retroperitoneal lymph node dissection. The arms are tucked, and the patient is padded and secured in a relatively supine position.

Figure 36-2. Port placement for laparoscopic retroperitoneal lymph node dissection. Four 10/12-mm, equally spaced trocars are placed in the midline.

counterpart. The patient must be secured to the operating table because tilt is needed to use gravity to help shift the bowel out of the operative field.

After intraperitoneal access is achieved (via a Veress needle or Hasson technique), four equally spaced, 10/12-mm laparoscopic ports are placed in the midline beginning 1 cm below the xiphoid process (Fig. 36-2). The umbilicus may not be incorporated as a port site. The large port size is essential to allow for the convenient introduction of larger (10/12-mm) instruments from varying angles. An additional 5-mm port may be placed in the midaxillary line midway between the iliac crest and ribs for additional retraction if needed. The bed is rotated maximally to allow optimal medialization of the bowel away from the operative field.

Right-Sided Dissection

The ascending colon is mobilized by incising the white line of Toldt from the pelvis and around the hepatic flexure. The second portion of the duodenum is identified and Kocherized, providing exposure of the retroperitoneum including the medial para-aortic space on the left.

Figure 36-3. Incision of posterior peritoneum circumferentially around the inguinal ring.

Spermatic Cord Dissection

The camera is moved to the second to the bottom trocar (trocar 3 in Fig. 36-2) to facilitate visualization during dissection of the spermatic cord stump. The peritoneum medial to the spermatic cord is incised, and the vas deferens is transected. The peritoneum is incised circumferentially around the inguinal ring (Fig. 36-3). With gentle traction on the cord, fibrous attachments and scar are incised until the suture on the spermatic cord is identified. The attachments are cut, and the cord is followed proximally along with surrounding nodal and fibroadipose tissue to the inferior vena cava (IVC). The ureter must be identified at all times to prevent inadvertent thermal injury. The spermatic vein and artery are ligated proximally and transected. The specimen is placed in an endobag and dropped on the contralateral side of the abdomen.

Lymphadenectomy

Although templates should be individualized to each case, we advocate removal of the right common iliac, paracaval, interaortocaval, preaortic, and medial para-aortic nodes (Fig. 36-4). Occasionally in obese patients (or when performing a full bilateral dissection), the left-most border of the dissection must be performed after rotating the table contralaterally to optimize exposure. The camera should be moved to the port second from the top. A paddle retractor is placed in the lowest trocar to protect and sweep the bowel medially.

The testicular vein stump is identified and minimally manipulated to prevent pseudoaneurysm formation with subsequent rupture. The tissues overlying the IVC are gently lifted and carefully incised longitudinally (Fig. 36-5). It is swept off the IVC in a “split and roll” fashion. Blunt dissection aids in further separating these lymphatic tissues toward and overlying the common iliac vessels inferiorly and renal hilum superiorly. Care must be taken to avoid injury of lower pole renal arteries, which are present in approximately 20% of cases, and accessory vessels crossing anterior to the IVC. The renal hilum is dissected to separate all fibroadipose tissue from the renal vein and artery as far under the IVC as possible. Next, the ureter is traced to its crossing over the common iliac vessels, and the lymphatic packet is separated from both of these structures.

Figure 36-4. Suggested templates for right (A) and left (B) therapeutic laparoscopic retroperitoneal lymph node dissection. These templates can be expanded or contracted based on each patient's tumor.

Figure 36-5. Fibrofatty tissue overlying the inferior vena cava being incised to initiate the “split and roll” technique. The duodenum has been reflected medially, and the spermatic vein stump has been clipped and divided.

The “split” tissue along the IVC is “rolled” medially to expose the retrocaval space. Lumbar vessels are identified, clipped, and divided to allow splitting of the posterior lymphatic tissues (Fig. 36-6). After this splitting is accomplished, the tissues are released from their attachment to the spine and delivered laterally. Great care is taken to separate the lymph nodes from the sympathetic chain and post-ganglionic nerve fibers. The aorta is identified next, and the tissues overlying it are similarly split to the level of the inferior mesenteric artery and rolled medially to enter the retroaortic space. The lumbar arteries may be controlled if additional mobility is needed to mobilize the interaortocaval packet posteriorly. The aorta can be medially retracted, facilitating para-aortic node excision with careful preservation of the sympathetic chain laterally. The interaortocaval nodes finally are removed to complete the dissection.

An important technical point is to leave a long stump on the aorta/vena cava side when ligating lumbar vessels such that they can be grasped and controlled in the event a clip dislodges. Lumbar vessels that retract into the iliopsoas uncontrolled usually can be managed with pressure or a figure-of-eight suture placed deep into the muscle. Lacerations of the IVC and aorta may occur during this operation but in most cases do not mandate open conversion. Direct pressure usually prevents excessive hemorrhage and can achieve hemostasis without the need for additional maneuvers. Adjunct hemostatic agents also can be used successfully in this circumstance. If the bleeding persists, or in the case of arterial bleeding, direct pressure can be used temporarily before definitive repair is undertaken with intracorporeal suturing.

Figure 36-6. The inferior vena cava is retracted to allow for lumbar vein ligation. Paracaval and precaval lymph nodes have been cleared.

Left-Sided Dissection

The peritoneum is incised lateral to the descending colon and along the splenic flexure. The colorenal ligaments are severed, and the bowel is bluntly dissected medially. The lateral attachments of the spleen are incised, and the tail of the pancreas is swept medially to ensure wide exposure of the retroperitoneum, including the medial paracaval space.

Spermatic Cord Dissection

Analogous to what is done on the right side, the spermatic cord stump suture is identified after circumscribing the peritoneum at the inguinal ring. The spermatic vein along with adjacent lymph nodes is traced proximally to the renal vein and the artery to the aorta where they are ligated and cut. The cord is placed in an endobag for removal at the conclusion of the procedure.

Lymphadenectomy

We advocate removal of the left common iliac, para-aortic, preaortic, interaortocaval, and medial paracaval lymph nodes (see Fig. 36-4). The dissection can be expanded as needed. Lumbar veins draining into the renal vein are clipped and divided to allow full dissection of the renal hilum. The vein is cleaned off medially to the junction of the vena cava. A paddle retractor in the lowest trocar aids in dissection. The renal artery is completely freed of all lymphatic tissues. Clips are generously used to avoid postoperative leakage of lymph. The tissues overlying the aorta are split from the renal hilum to the level of the inferior mesenteric artery. Care should be taken to identify the right spermatic artery to avoid avulsion. In contrast to the tissues overlying the vena cava, the preaortic space may include postganglionic sympathetic nerves; care must be taken to separate the nodal tissue while preserving these nerves (Fig. 36-7). The ureter and common iliac vessels are separated from all fibroadipose tissue. The preaortic tissues are rolled medially down to the lumbar arteries. The lumbar vessels are controlled and cut, allowing excision of the retroaortic lymph nodes. The vena cava is identified, and using a “split and roll” approach, the paracaval, precaval, and interaortocaval lymph nodes are removed in the same manner as for a right-sided dissection. Care should be taken to identify any right-sided renal arteries to avoid inadvertent ligation.

Figure 36-7. The sympathetic chain and efferent nerves are seen spared, while para-aortic and preaortic lymph nodes have been removed.

In patients who have had chemotherapy, it may be necessary to ligate and transect the inferior mesenteric artery. If suspect nodes are detected, the node dissection can be expanded to perform a complete bilateral dissection; this can be performed from the same side using retraction.

At the conclusion of the operation, the lymph nodes are placed in an endobag and extracted. Each packet should be placed in a separate sac during dissection to help increase yield of nodal evaluation and count. The retroperitoneum is irrigated with warm water, and lymphostasis and hemostasis are ensured. The bowel and adjacent organs (liver, gallbladder, kidneys, ureters, pancreas, and spleen) are inspected carefully for injury. The trocar sites are closed with fascial sutures using a Carter-Thomason device. A drain is not routinely used.

Bilateral Laparoscopic Retroperitoneal Lymph Node Dissection

Bilateral dissections may be performed when necessary and usually can be undertaken without a change in patient positioning. When the side of primary tumor is completed with the templates described, a small amount of tissue is left just medial to the contralateral ureter and inferiorly toward the common iliac vessels. These tissues are dissected free, and a bilateral dissection is completed. It is easier to approach a bilateral dissection from the right side.

Robotic-Assisted Retroperitoneal Lymph Node Dissection Port Placement and Technique

For RA-RPLND, we place the patient in a modified flank position, and the port locations are similar to the locations used in robotic renal surgery, with the ports shifted slightly caudally to assist in the iliac nodal dissection (Fig. 36-8). Use of the robotic fourth arm is preferred for improved retraction leaving the surgeon two working instruments. One or two 12-mm assistant ports may be used depending on surgeon preference. The general steps of the operation mirror the open and laparoscopic techniques. The robotic clip

Figure 36-8. Port placement for robotic-assisted retroperitoneal lymph node dissection. Yellow indicates camera port, green indicates 8-mm robotic ports, and red indicates 12-mm assistant ports. ASIS, anterior superior iliac spine.

applier allows the surgeon to articulate the instrument while placing clips and can be particularly helpful in securing lumbar vessels. Depending on body habitus, dissection of the spermatic cord to the orchiectomy suture may require re-docking of the robotic arms and triangulating them toward the inguinal ring for a more direct approach to this area. An alternative technique has been described and entails placement of the patient in a steep Trendelenburg supine position with the robot docking from the patient's head (de Cobelli et al, 2013). The ports are placed in positions similar to robotic-assisted radical prostatectomy, but the field of dissection is reversed (toward the head).

POSTOPERATIVE CARE

Patients are extubated and transferred to the recovery area without nasogastric tube drainage. The patient may ambulate and resume a liquid diet the night of surgery. Postoperative tachycardia may occur secondary to sympathetic stimulation (Bahnon et al, 1989). Most patients can be discharged on postoperative day 1. Some surgeons advocate consumption of a low-fat diet for 1 to 2 weeks postoperatively.

PROSPECTIVE NERVE-SPARING TECHNIQUES

As in open RPLND, nerve-sparing techniques involve prospectively identifying, dissecting, and preserving the sympathetic chains, hypogastric plexus, and postganglionic fibers. With experience, these tissues can be readily identified as more fibrous compared with lymphatic tissue. On the right side, the postganglionic sympathetic fibers are most easily identified behind the IVC as they cross anterior to the aorta to insert in the hypogastric plexus. Their takeoff from the sympathetic chains is always near lumbar veins, so great care should be taken in clipping lumbar vessels. On the left side, it is easiest to identify the postganglionic sympathetic nerves at the ganglia as they leave the sympathetic chain and dissect them prospectively as they course anterior to the aorta before joining the hypogastric plexus. Care should be taken to avoid energy sources such as electrocautery when dissecting nerve fibers (Peschel et al, 2002; Bhayani et al, 2003; Abdel-Aziz et al, 2006; Steiner et al, 2008).

COMPLICATIONS

The most common reason for conversion to an open procedure is uncontrollable bleeding, and vascular injury is cited as the most common intraoperative complication (Bhayani et al, 2003;

Abdel-Aziz et al, 2006; Neyer et al, 2007; Kenney and Tuerk, 2008). Although bleeding and open conversion occurred frequently in older series, it is less common in more recent series. In most contemporary series, the open conversion rate is less than 5%, but it has been reported as high as 11.8% (Rassweiler et al, 2000; Neyer et al, 2007; Nielsen et al, 2007; Cresswell et al, 2008; Skolarus et al, 2008). Conversion to an open procedure should never be viewed as a failure, and surgeons should be familiar with open RPLND should it be required. Injury to major abdominal viscera also has been reported but appears to be a rare event (Neyer et al, 2007; Kenney and Tuerk, 2008).

Postoperative complication rates of 9% to 25% have been reported in contemporary series (Albqami and Janetschek, 2005; Neyer et al, 2007; Nielsen et al, 2007; Cresswell et al, 2008; Skolarus et al, 2008). Reported complications include chylous ascites, ileus, lymphocele, nerve injury, pulmonary embolus, *Clostridium difficile* colitis, retroperitoneal hematoma, and ureteral injury (Kenney and Tuerk, 2008). Retrograde ejaculation is a potential long-term source of morbidity for patients undergoing open RPLND and L-RPLND. The rates of retrograde ejaculation have been consistently low with the laparoscopic approach and range from 0% to 14% (Albqami and Janetschek, 2005; Neyer et al, 2007; Nielsen et al, 2007; Cresswell et al, 2008; Skolarus et al, 2008; Steiner et al, 2008). With meticulous ligation of lymphatic channels, the incidence of chylous ascites should be less than 2%. A summary of the morbidity of L-RPLND in the management of clinical stage I NSGCT is provided in Table 36-1. Although it is difficult to compare these data retrospectively with published open RPLND series, they appear to compare favorably. In one study of open primary RPLND, a 6% transfusion rate with a mean length of stay of 6 days was reported (Subramanian et al, 2010). Similar to L-RPLND, vascular injury was the most common intraoperative complication (4.5% of cases); 2 patients developed chylous ascites (1.8%) and 14 (12.5%) had an ileus. Antegrade ejaculation in this group of patients was 80%, and seven patients (6.3%) required reoperation (for small bowel obstruction [two patients], incisional hernia repair [four patients], and ureteral reconstruction [one patient]). Two patients required nephrectomy, one for a dysplastic kidney and the other for oncologic reasons.

The morbidity and open conversion rate of L-RPLND after chemotherapy is higher and seems to be experience dependent as well. Early series cited major complication rates of more than 50% (Palese et al, 2002) and high conversion rates (Rassweiler et al, 1996). However, similar to primary L-RPLND, more recent series from experienced centers show improvement in these parameters (Steiner et al, 2004; Permpongkosol et al, 2007). Steiner and colleagues (2004) reported on 68 L-RPLND procedures performed after chemotherapy and reported no open conversions. In another more limited report including 17 patients who underwent L-RPLND after chemotherapy, the authors reported no complications, transfusions, or open conversions (Maldonado-Valadez et al, 2007). Studies report preservation of antegrade ejaculation with experience (LeBlanc et al, 2001; Albqami and Janetschek, 2005; Corvin et al, 2005).

RESULTS AND CURRENT STATUS

There are no randomized trials comparing open RPLND and L-RPLND. Retrospective assessments suggest that patients undergoing L-RPLND have a significantly shorter hospital stay, decreased blood loss, greater quality-of-life scores, and faster return to normal activities (Janetschek et al, 1996; Abdel-Aziz et al, 2006; Poulakis et al, 2006). Results of RA-RPLND are limited to early reports demonstrating safety and feasibility.

Laparoscopic Retroperitoneal Lymph Node Dissection for Clinical Stage I Disease

Published reports of L-RPLND with long-term follow-up suggest that it is an effective treatment option for patients with low-stage

NSGCTs (Table 36-2). The staging accuracy of L-RPLND has been documented and consistent with open series in that 25% to 30% of men with clinical stage I NSGCT are found to harbor occult nodal disease. A study with a mean follow-up of 7 years included 87 patients with clinical stage I disease and revealed a 9% and 0% relapse rate for patients with pN0 and pN+ disease, respectively, with all patients alive and free of disease at last follow-up (Cresswell et al, 2008). The two retroperitoneal recurrences (2.5%) in this series occurred outside the dissection template, and all patients with pN+ disease were administered adjuvant chemotherapy. Examination of other large L-RPLND series confirms these findings, and recurrence rates and their patterns in this patient population are comparable to those of open RPLND series. The recurrence rate of patients found to have negative lymph nodes at L-RPLND is reported between 0% and 10%, which compares favorably with open RPLND series (Donohue et al, 1993; Hermans et al, 2000).

Despite the favorable long-term outcomes, the practice of universal chemotherapy in the adjuvant setting in patients with clinical stage I disease who are also harboring metastatic disease at L-RPLND has been the focus of critics who question the therapeutic efficacy of the technique. Approximately 70% of men found to have pN1 disease and who undergo a properly performed RPLND are cured and can avoid chemotherapy (Richie and Kantoff, 1991; Donohue et al, 1993; Rabbani et al, 2001). However, patients found to have pN1 disease can opt to receive two cycles of chemotherapy in the adjuvant setting with excellent long-term results rather than risk receiving three or four cycles of chemotherapy should they experience relapse. The decision to administer chemotherapy to patients with pN1 disease is a matter of preference and factors in the philosophy of the urologist and medical oncologist as well as the patient.

A report of 120 patients undergoing L-RPLND at one of four institutions in the United States included 10 patients with pathologic stage II disease who underwent surveillance (Nielsen

et al, 2007). At a mean follow-up of 34.8 months, none of the patients had experienced a retroperitoneal recurrence. **Additional reports omitting chemotherapy for patients with pN1 disease who underwent L-RPLND support its therapeutic efficacy, but further studies and follow-up are required (Skolarus et al, 2008; Steiner et al, 2008).**

The adequacy of L-RPLND also can be evaluated by examining patients found to have pathologic stage I disease. If L-RPLND was inadequate, certain patients with pathologic stage II disease would be mislabeled as having pathologic stage I disease, and a retroperitoneal recurrence would result. This supposition has not occurred because no retroperitoneal recurrence has resulted in a series of therapeutic L-RPLND where a full dissection has been performed (Bhayani et al, 2003; Porter and Lange, 2003; Nielsen et al, 2007; Skolarus et al, 2008; Steiner et al, 2008). The therapeutic efficacy of L-RPLND will continue to be tested as more patients found to have pathologic stage II disease are choosing observation after this technique with good results.

Laparoscopic Retroperitoneal Lymph Node Dissection for Clinical Stage II

Fewer reports exist examining the role of L-RPLND for patients with clinical stage II NSGCTs as a primary modality or in the postchemotherapeutic setting. Data regarding the use of primary L-RPLND in patients with clinical stage IIA disease are limited. Several authors have reported on the use of L-RPLND in the postchemotherapeutic setting (see Table 36-2). Albqami and Janetschek (2005) reported their experience with 59 patients with stage IIB or IIC disease who underwent L-RPLND after chemotherapy: Of the 43 patients with preoperative stage IIB disease with a mean follow-up of 53 months, 1 experienced a recurrence 24 months postoperatively along the external iliac nodes, outside the original template. Another group

L-RPLND, laparoscopic retroperitoneal lymph node dissection; Lt, left; NSGCT, nonseminomatous germ cell tumor; pN+, histologically positive lymph nodes; Rt, right.

(Maldonado-Valadez et al, 2007) reported on 17 patients and demonstrated the feasibility of L-RPLND after chemotherapy: Viable tumor was found in 3 patients, 2 of whom experienced retroperitoneal recurrences. Full bilateral RPLND, which is typically recommended in this setting, was not performed in these series (Stephenson and Sheinfeld, 2004).

Keeping in line with the goals of open RPLND performed after chemotherapy, Steiner and associates (2008) performed bilateral nerve-sparing L-RPLND on 19 postchemotherapy patients with stage IIB disease. The authors found teratoma in 4 patients, necrosis/fibrosis in 14 patients, and active tumor in 1 patient. This study included two patients with clinical stage IIA disease who underwent L-RPLND without adjuvant chemotherapy. No retroperitoneal recurrences were noted in either group at 17 months of follow-up. Longer follow-up and larger series are required to evaluate the efficacy of L-RPLND in the postchemotherapeutic setting.

SUMMARY

L-RPLND has been demonstrated to be a feasible, safe, and effective treatment option for men with clinical stage I NSGCT when performed at large-volume institutions by experienced laparoscopic surgeons. L-RPLND has evolved into a therapeutic operation duplicating the open procedure, with reports demonstrating efficacy and minimal morbidity. Data regarding L-RPLND for clinical stage II disease and for patients who have received chemotherapy are limited and associated with a longer learning curve. Early reports suggest that robotic-assisted surgery is emerging as yet another minimally invasive alternative to RPLND.

KEY POINTS

- L-RPLND aims to decrease operative morbidity while duplicating the open approach.
- The most common reason for conversion to an open procedure is bleeding, although this is a rare complication (<5%).
- L-RPLND is an effective treatment option for patients with low-stage NSGCTs.
- Reports omitting chemotherapy for patients with N1 disease who underwent L-RPLND support its therapeutic efficacy, but more studies and follow-up are required.
- RA-RPLND is emerging as another minimally invasive alternative to open RPLND.

Premalignant Cutaneous Lesions

Squamous Cell Carcinoma

Surgical Management of the Primary Tumor

Treatment of the Inguinal Nodes

Radiation Therapy

Chemotherapy

Nonsquamous Penile Malignant Neoplasms

Cancers of the penis are uncommon tumors that are often devastating for the patient and frequently diagnostically and therapeutically challenging for the urologist. Although rare in North America and Europe, penile malignant neoplasms constitute a substantial health concern in many African, South American, and Asian countries.

Any discussion of penile cancers must begin by addressing both premalignant and malignant tumors of the penis. A description of these lesions serves to establish their anatomic, etiologic, and histologic relationship to squamous cell carcinoma, which is the most common malignant tumor of the penis, as well as to other malignant neoplasms that involve the penis. Developments in the etiologies of various premalignant and malignant penile tumors are reviewed in this chapter.

In this chapter, we review the epidemiology, etiology, and natural history of squamous carcinoma and its contemporary management. Reports have confirmed the importance of pathologic stage and histologic features of the primary tumor as well as the presence and extent of lymph node metastasis in determining prognosis and treatment planning for penile squamous carcinoma (Ravi, 1993a; McDougal, 1995; Theodorescu et al, 1996; Pizzocaro et al, 1997; Slaton et al, 2001). In addition, developments in staging of the disease, including novel imaging modalities and the use of dynamic sentinel node biopsy (DSNB), and modified surgical approaches to improve staging accuracy and reduce potential morbidities are presented. The selection of patients for organ-preserving surgical strategies is discussed.

The role of radiation therapy as both a primary treatment and a palliative measure is reviewed. Contemporary developments in chemotherapy as well as in combination therapy with multiple therapeutic modalities are also discussed. A contemporary scheme for the management of the inguinal region, based on histologic and clinical features, is presented.

Finally, the various nonsquamous malignant neoplasms that may involve the penis are reviewed and discussed.

PREMALIGNANT CUTANEOUS LESIONS

Please see the Expert Consult website for a discussion of premalignant cutaneous lesions (including Fig. 37-1), and virus-related dermatologic lesions.

SQUAMOUS CELL CARCINOMA

Carcinoma in Situ

Carcinoma in situ (Tis) of the penis is called *erythroplasia of Queyrat* by urologists and dermatologists if it involves the glans penis and prepuce or Bowen disease if it involves the penile shaft or the remainder of the genitalia or perineal region. This nomenclature has served to separate carcinoma in situ from the mainstream of thinking and reporting of penile carcinoma. However, the epidemiology and natural history of this lesion parallel those of early carcinoma of the penis, and carcinoma in situ can progress to invasive carcinoma.

The erythroplasia originally described by Queyrat in 1911 consists of a red, velvety, well-marginated lesion of the glans penis or, less frequently, the prepuce of the uncircumcised man (Aragona et al, 1985). It may ulcerate and may be associated with discharge and pain. On histologic examination the normal mucosa is replaced by atypical hyperplastic cells characterized by disorientation, vacuolation, multiple hyperchromatic nuclei, and mitotic figures at all levels. The epithelial rete extends into the submucosa and appears elongated, broadened, and bulbous. The submucosa shows capillary proliferation and ectasia with a surrounding inflammatory infiltrate that is usually rich in plasma cells. These microscopic features distinguish erythroplasia of Queyrat from chronic localized balanitis. HPV has been identified in penile carcinoma in situ (Pfister and Haneke, 1984). Progression to invasive carcinoma can occur in 10% to 33% of patients (Buechner, 2002; Bleeker et al, 2009).

In 1912 Bowen described an intraepithelial neoplasm of the skin associated with a high occurrence of subsequent internal malignant disease as a distinct entity. Bowen disease and erythroplasia of Queyrat are histologically similar (Graham and Helwig, 1973) (see Fig. 37-1C on the Expert Consult website). Both tumors are characterized by the noninvasive changes of carcinoma in situ. Visceral malignant disease is not associated with erythroplasia of Queyrat, and subsequent case-control studies have shown no association of Bowen disease with internal malignant tumors (Anderson et al, 1973). Thus penile carcinoma in situ does not in itself warrant a specific search for internal malignant tumors. Bowen disease is characterized by sharply defined plaques of scaly erythema on the penile shaft. Crusted or ulcerated variants can occur. The appearance can be confused with Bowenoid papulosis, nummular eczema, psoriasis, and superficial basal cell carcinoma. If it is not treated, then invasive carcinoma may arise in about 5% of patients (Buechner, 2002). When all cases of carcinoma in situ

- When in doubt, biopsy of penile lesions should be considered to establish a diagnosis.
- Lesions associated with the development of penile carcinoma that require treatment or close follow-up include cutaneous horn, balanitis xerotica obliterans, and pseudoepitheliomatous micaceous and keratotic balanitis.

Some histologically benign penile lesions have been recognized as having malignant potential or close association with the development of squamous carcinoma. In one large series, 42% of patients with squamous cell cancer had a history of preexisting penile lesions (Bouchot et al, 1989). Although the incidence of progression of these lesions to squamous cell carcinoma is not known, all have been associated with the disease. Premalignant penile lesions have now been divided into two broad categories based on their potential causation by human papillomavirus (HPV) or inflammatory pathways (reviewed in Shabbir et al, 2011b).

Non-Human Papillomavirus-Related Penile Premalignant Lesions

Cutaneous Horn

The penile cutaneous horn is a rare lesion. It usually develops over a preexisting skin lesion (wart, nevus, traumatic abrasion, or malignant neoplasm) and is characterized by overgrowth and cornification of the epithelium, which forms a solid protuberance. On microscopic examination, extreme hyperkeratosis, dyskeratosis, and acanthosis are noted. It is associated with HPV type 16. Treatment consists of surgical excision with a margin of normal tissue about the base of the horn. These lesions may recur and may demonstrate malignant change on subsequent biopsy, even when initial histologic appearance is benign (Fields et al, 1987). Because this tumor may evolve into a carcinoma or may develop as a result of an underlying carcinoma, careful histologic evaluation of the base and close follow-up of the excision site are essential (Fig. 37-1A) (Pressman et al, 1962; Hassan et al, 1967; Solivan et al, 1990).

Pseudoepitheliomatous Micaceous and Keratotic Balanitis

Pseudoepitheliomatous micaceous and keratotic balanitis is an unusual lesion that manifests as hyperkeratotic, micaceous growths on the glans and may have some of the microscopic features of verrucous carcinoma (see Chapter 16, Fig. 16-41). They tend to recur and may represent an early form of that tumor (Jenkins and Jakubovic, 1988; Gray and Ansell, 1990). Treatment includes excision, laser ablation, or cryotherapy. These lesions require aggressive treatment and close follow-up. Fibrosarcoma of the glans after treatment of a pseudoepitheliomatous micaceous and keratotic balanitis lesion with cryotherapy has been reported (Irvine et al, 1987).

Male Lichen Sclerosus (Balanitis Xerotica Obliterans)

Male lichen sclerosus (LS) (balanitis xerotica obliterans), a genital variation of lichen sclerosus et atrophicus, manifests as a whitish patch on the prepuce or glans, often involving the meatus and sometimes extending into the fossa navicularis (see Chapter 16, Fig. 16-12). The lesions may be multiple and may assume a mosaic appearance. The meatus may appear white, indurated, and edematous. Glanular erosions, fissures, and meatal stenosis may occur. The disorder is most common in uncircumcised men and occurs most commonly in middle-aged men, but it does occur in boys (McKay et al, 1975). Symptoms include pain, dyspareunia, pruritus, painful erections, and urinary obstruction (Bainbridge et al, 1971).

On histologic examination, these lesions show an atrophic epidermis with loss of the rete pegs and homogenization of collagen on the upper third of the dermis combined with a zone of lymphocytic and histiocytic infiltration. They resemble the lesions of lichen sclerosus et atrophicus found elsewhere (Laymon and Freeman, 1944). There are reports documenting the association of male LS with squamous cell carcinoma as well as with the development of carcinoma long after a lesion of LS has been treated (Laymon

Figure 37-1. A, Cutaneous horn with underlying well-differentiated squamous carcinoma. B, Buschke-Löwenstein tumor. C, Bowen disease involving penile shaft skin.

and Freeman, 1944; Bart and Kopf, 1978; Jamieson et al, 1986; Dore et al, 1990; Simonart et al, 1998; Velazquez and Cubilla, 2003; Kumaran and Kanwar, 2004). It is a frequent finding in conjunction with squamous penile cancer, noted in 28% to 50% of patients. Penile cancer was subsequently diagnosed in 2.3% to 5.8%

of men with LS in two different series (Nasca et al, 1999; Powell and Wojnarowska et al, 1999; Depasquale et al, 2000; Pietrzak et al, 2006). Cubilla and coworkers (2004) describe a well-differentiated nonverruciform variant of squamous cell carcinoma associated with lichen sclerosus et atrophicus that preferentially involves the prepuce. The cause of male LS is unknown; however, a recent study identified *Borrelia burgdorferi* infection in affected tissues in the early course of the disease. Floating microscopy was used to examine specimens from 60 patients with LS, and *B. burgdorferi* species were identified in 63% of the LS tissues and none of the controls (Eisenle et al, 2008). Whether this organism is causative is unproven at this time and requires additional study.

Treatment involves clobetasol propionate cream for 2 to 3 months (Pugliese et al, 2007). Meatal stenosis is a common problem often requiring repeated dilations, corticosteroid injection, or even formal reconstructive surgery (Poynter and Levy, 1967). Close follow-up is essential, with biopsy if a change in appearance or behavior occurs.

Virus-Related Penile Lesions

There is increasing evidence to suggest that a number of penile lesions share viral causes. Condyloma acuminatum and bowenoid papulosis appear to be related to infection with HPV. Human herpesvirus 8, also known as *Kaposi sarcoma-associated herpesvirus*, is strongly suspected of being the causative agent of epidemic (acquired immunodeficiency syndrome [AIDS]-related) Kaposi sarcoma (Miller et al, 1996; Simpson et al, 1996; Jaffe and Pellett, 1999; Dianzani et al, 2004).

Human Papillomavirus in Malignant Transformation

Condylomata acuminata are soft, papillomatous growths typically considered to be benign (see Chapter 16, Fig. 16-21G). Also known as *genital warts* or *venereal warts*, they have a predilection for the moist, glabrous areas of the body and the mucocutaneous surfaces of the perineal and genital areas. The lesions are soft and friable and may occur singly on a pedicle or in a moruloid cluster on a broad base. These lesions are rare before puberty (Redman and Meacham, 1973; Copulsky et al, 1975) and when encountered may suggest sexual abuse (Handly et al, 1993).

In the male, condylomata occur most commonly on the glans, the penile shaft, and the prepuce. The meatus should also be carefully inspected. Lesions recur frequently, both in new and in previously treated sites. Approximately 5% of patients will demonstrate urethral involvement, which may extend to the prostatic urethra (Culp et al, 1944). Rarely, extreme involvement of the urethra may require urethroplasty (Feneley et al, 1992). Bladder involvement, although rare, is extremely difficult to treat effectively (Bissada et al, 1974).

On microscopic examination, condylomata acuminata demonstrate an outer layer of keratinized tissue covering papillary fronds, which are supported by connective tissue stroma. The epithelial layer consists of well-ordered rows of squamous cells. A dermal lymphocytic infiltrate is usually present. Treatment of these lesions with podophyllin may induce histologic changes suggestive of carcinoma (King and Sullivan, 1947). Consequently, preliminary biopsy of large lesions that appear to be condylomata acuminata should precede any treatment with topical podophyllin.

Interest in genital condylomata has increased dramatically, stimulated by an increased understanding of the relationship between HPV infection and certain human cancers. The terms *genital condyloma*, *venereal warts*, *genital warts*, and *genital HPV infection* all refer to a sexually transmitted disease caused by HPV. Although HPV is not a reportable sexually transmitted disease, a current estimate puts the number of new infections at 500,000 to 1 million annually (Stone, 1989). A study of 463 men aged 18 to 40 years analyzed samples from the glans and corona, penile shaft, scrotum, urethra, perianal area, anal canal, and semen and detected HPV in 51.2% (Nielson et al, 2007). Giuliano and colleagues (2009) found the prevalence of HPV in U.S. males to be

51.7%, in Brazilian men to be 69.4%, and in Mexican men to be 56.1%. In a study of 379 adult heterosexual males, HPV infection was localized to the penile shaft (52%), scrotum (40%), glans or corona (32%), urine (10%), and semen (6%) (Hernandez et al, 2008). In a cohort of 379 adult heterosexual males, the overall incidence of HPV infection was 52%, with 60% of the uncircumcised and 50% of the circumcised males found to have HPV infection. There was a higher prevalence of oncogenic HPV in the uncircumcised group (Hernandez et al, 2008). Factors associated with higher rates of infection with HPV include presence of foreskin, increasing numbers of sexual partners, lack of condom use, and smoking (Giuliano et al, 2009).

The overall prevalence of HPV in females was found to be 26.8% among U.S. females aged 14 to 59 years and highest among women aged 20 to 24 years (44.8%) (Dunne et al, 2007). HPV is recognized as the principal causative agent in cervical dysplasia and cervical cancer (Lancaster et al, 1986; Alani and Munger, 1998; Gross and Pfister, 2004). Significant numbers of male partners of women with cervical condylomata will have lesions not identified on simple inspection and may not be aware that they are infected or have the potential to infect others (Sedlacek et al, 1986).

On histologic examination, the koilocyte—a cell characterized by an empty cavity surrounding an atypical nucleus—is pathognomonic for HPV infection (Schneider, 1989). DNA hybridization techniques have been used to identify and classify HPV infections, and some 60 genotypes of HPV virus have been identified that involve the genital tract (Nielson et al, 2007). Virus types 6, 11, and 42 to 44 are associated with gross condylomata and low-grade dysplasia. Types 16, 18, 31, 33, 35, and 39 have a higher association with malignant disease (Smotkin, 1989). More recently, reports have suggested that tumor virus transforming proteins from HPV types 16 and 18, particularly the E6 and E7 proteins, may target tumor suppressor gene products pRB and TP53 and may be the causative agents in a subset of penile cancers (Levi et al, 1998; Griffiths and Mellon, 1999). E6 appears to bind to cellular tumor suppressor protein TP53, leading to its rapid degradation, resulting in chromosome instability, DNA mutations, and aneuploidy. E7 binds to and phosphorylates the pRB retinoblastoma protein, leading to the release of transcription factor E2F that activates mitosis (zur Hausen, 1996). Human immunodeficiency virus (HIV) infection may predispose affected patients to rapid development of squamous carcinoma from preexisting condyloma infection (Sanders, 1997).

Subclinical disease may be detected by the application of 5% acetic acid solution to the penis, followed by inspection with a magnifying glass. Lesions will turn white, and flat lesions often invisible on regular inspection may be detected. These acetowhite lesions are not always caused by HPV, and biopsy must be performed to confirm the diagnosis (Krebs and Schneider, 1987). Careful inspection of the base of the shaft, the scrotum, and the inguinal folds is essential. The meatus should be examined; if lesions are present, urethroscopy should be performed (Culp et al, 1944; Barrasso et al, 1987).

A variety of treatments for genital warts are available, but none has been proven to reduce transmission to sexual partners nor to prevent progression to dysplasia or cancer. In addition, recurrence after treatment is quite common. The more commonly used treatments include (1) podophyllotoxin 0.5% solution or gel, (2) trichloroacetic acid 35% to 85%, (3) cryotherapy with liquid nitrogen, (4) electrofulguration, (5) CO₂ laser therapy, and (6) imiquimod 5% cream (Buechner, 2002; Dupin, 2004).

The goal of surgical therapies is to either remove or ablate condylomata. Circumcision will remove preputial lesions, gain exposure for treatment, and allow post-treatment monitoring. Fulguration and excision may be advisable to avoid large areas of maceration, ulceration, and secondary infection.

Surgical therapy with use of a pediatric resectoscope may be helpful in debulking large intraurethral lesions. The lowest power required to resect the lesions should be used, and electrocautery should be minimized to avoid the development of urethral stricture. Whether laser therapy, electrocautery, or cryotherapy is used,

significant rates of recurrence have been noted within the first 6 months after treatment (i.e., 40% to 80%; Dupin, 2004).

Topical podophyllin (Condylox 0.5%) or trichloroacetic acid has been a well-established and often successful treatment for small condyloma lesions (Culp et al, 1944; Kinghorn et al, 1993). More recently, however, imiquimod cream (5%) has become the topical treatment of choice for condyloma. Imiquimod is an immune modulator that enhances natural killer cell activity (Buechner, 2002; Sanchez-Ortiz and Pettaway, 2003). It is important to note that immune modulators and antiviral agents have the potential to affect the viral load.

Various interferons have been used in condyloma treatment (Geffen et al, 1984). A randomized study has shown that short-term intralesional interferon alfa-2b has activity against condyloma (Eron et al, 1986). The outcome of studies using other interferons has been less clear (Zouboulis et al, 1991). Interferon therapy continues to be reserved for extensive and recalcitrant lesions (Krebs, 1989a, 1989b; Ferenczy, 1990).

Another recent antiviral agent shown to have activity against HPV includes (S)-1-(3-hydroxy-2-phosphonylmethoxypropyl) cytosine (cidofovir), an acyclic nucleoside phosphonate with broad-spectrum antiviral activity against DNA viruses. A 1% gel preparation of cidofovir applied daily every other week for six cycles was shown to be superior to placebo in a double-blind placebo-controlled trial, with a complete response of 47% in treated patients (Snoeck et al, 2001).

Intraurethral lesions may be extremely difficult to treat. 5-Fluorouracil cream applied weekly for 3 weeks has been successful in eliminating urethral lesions (Bissada et al, 1974; Dretler and Klein, 1975; Boxer and Skinner, 1977). Care must be taken to work the cream down the urethra and to avoid exposure of the scrotal skin. Use of a scrotal support or zinc oxide cream may be helpful. The addition of 5-fluorouracil cream to laser therapy did not improve the success rate in one study (Carpiniello et al, 1987).

HPV infection is common and, as noted earlier, potentially carcinogenic. Condylomata have been associated with squamous cell carcinoma of the penis (Beggs and Spratt, 1964; Dawson et al, 1965; Rhatigan et al, 1972). Malignant transformation of condyloma to squamous cell carcinoma has been reported (Boxer and Skinner, 1977; Coetzee, 1977; Malek et al, 1993). Condylomata acuminata located in the perianal, scrotal, and oral areas have also demonstrated malignant degeneration (Siegel, 1962; Burmer et al, 1993). An increased incidence of penile intraepithelial neoplasia has been found in the male partners of women with cervical intraepithelial neoplasia (Barrasso et al, 1987; Iversen et al, 1997). Thus preventive strategies are relevant. A quadrivalent vaccine (Gardasil, approved by the U.S. Food and Drug Administration [FDA], June 2006) that protects against HPV types 5, 11, 16, and 18 in women ages 9 to 26 years (Watson et al, 2008) has become available. In 2010 the same vaccine was approved for use in males ages 9 to 26 for the prevention of both anal and genital lesions (Sun, 2010). In one study the efficacy of preventing HPV-related genital lesions was 65% (Giuliano et al, 2011). Vaccination consists of a series of three injections over 6 months (Hoffner, 2009). In 2010 it was estimated that only about one third of eligible females received the vaccine (Centers for Disease Control and Prevention, 2011).

Bowenoid Papulosis

Carcinoma in situ of the penis has been well recognized since its first description by Queyrat in 1911. Kopf and Bart described bowenoid papulosis, a condition having a histologic appearance similar to that of carcinoma in situ but a benign course, in 1977.

Bowenoid papulosis manifests as multiple papules on the penile skin or female vulva, usually during the second or third decade of life. The lesions are usually pigmented and range from 0.2 to 3.0 cm in diameter, and smaller lesions may coalesce into larger ones (Patterson et al, 1986). Pigmented lesions occur on the penile skin, whereas glanular lesions tend to be flat papules (Gross et al, 1985). Diagnosis is confirmed by biopsy (Peters and Perry, 1981). These lesions meet all the histologic criteria of carcinoma in situ but

display differing growth patterns relative to flat, endophytic, or exophytic clinical appearance (Wade et al, 1978; Peters and Perry, 1981; Gross et al, 1985; Patterson et al, 1986; Bhojwani et al, 1997). DNA sequences suggestive of HPV-16 have been found in specimens of bowenoid papulosis, and a causative role for HPV is suspected (Gross et al, 1985; Endo et al, 2003). Whereas histologically this condition is a carcinoma in situ, the clinical course of bowenoid papulosis is invariably benign (Su and Shipley, 1997).

Treatment has included electrodesiccation, cryotherapy, laser fulguration, topical 5-fluorouracil cream, and excision with skin grafting.

Kaposi Sarcoma

Kaposi sarcoma, first described in 1972, is a tumor of the reticuloendothelial system (Kaposi, 1982). It appears as a cutaneous neovascular lesion, a raised, painful, bleeding papule or ulcer with bluish discoloration. On histologic examination the tumor is vasoformative with endothelial proliferation and spindle cell formation.

Initially, Kaposi sarcoma occurred rarely in Europe and North America. It was characterized by a slowly progressive tumor affecting the lower extremities of older men, usually of Eastern European Jewish or Italian descent. Kaposi sarcoma was also found in young black African men and patients receiving immunosuppressive therapy. The disease is now closely linked with patients who have AIDS and takes a much more aggressive clinical course in this group.

Kaposi sarcoma is now subcategorized as follows: (1) classic Kaposi sarcoma, which occurs in patients without known immunodeficiency and has an indolent and rarely fatal course; (2) immunosuppressive treatment-related Kaposi sarcoma, which occurs in patients undergoing immunosuppressive therapy for organ transplantation or other indications and is often reversed with dosage modification of the immunosuppressive agents; (3) African Kaposi sarcoma, which occurs in young men and may be indolent or aggressive in course; and (4) epidemic or HIV-related Kaposi sarcoma, which occurs in the patient with AIDS.

The classic and immunosuppressive forms of the disease are considered nonepidemic. Nonepidemic Kaposi sarcoma limited to penile involvement should be aggressively treated because it is rarely associated with diffuse organ involvement. Localized surgical excision or small-field external-beam or electron beam radiation has been effective (Lands et al, 1992). With wider areas of involvement, partial penectomy is indicated. In the immunosuppressed patient Kaposi sarcoma will often regress with the discontinuation of immunosuppressive therapy. If regression does not occur, local excision or radiation should be considered. Systemic management for multisystem involvement has employed interferon and cytotoxic therapy (National Cancer Institute Position Statement, 1990).

In the patient with AIDS, the underlying immunodeficiency predisposes the host to Kaposi sarcoma by a factor of 7000 (Miles, 1994). The first case of HIV-related epidemic Kaposi sarcoma was reported in 1981 (Friedman-Kien, 1981) and the first with penile involvement in 1986 (Seftel et al, 1986). Subsequently, Kaposi sarcoma of the penis has become a relatively common lesion in the patient with AIDS. Penile involvement is more common in homosexual men than in others with AIDS. In the first 1000 cases of AIDS reported by the Centers for Disease Control and Prevention, incidence of penile Kaposi sarcoma was 44% in homosexual and bisexual patients compared with only 16% in intravenous drug abusers with AIDS and 0% of hemophiliac patients with AIDS (Jaffe et al, 1983; Bayne and Wise, 1988). Several reports suggest a strong relationship between infection with human herpesvirus 8, also known as *Kaposi sarcoma-related herpesvirus*, and the development of Kaposi sarcoma lesions in patients with HIV infection (Jaffe and Pellett, 1999; Sitas et al, 1999). Some studies have found epidemic Kaposi sarcoma in patients who are HIV negative, which suggests that certain sexual practices and a separate sexually transmitted agent may be responsible for this form of the disease (Miles, 1994; Chitale et al, 2002). Human herpesvirus 8 has been isolated

from penile Kaposi lesions in patients who were HIV negative, which supports the notion that this disease may be sexually transmitted potentially via homosexual practices (Morelli et al, 2003).

Whereas Kaposi sarcoma may be the presenting sign of the disease in many patients with AIDS, early involvement of the penis is rare in this group (Grunwald et al, 1994). Treatment is directed toward palliation (Lowe et al, 1989). Glans penis or corpus spongiosum involvement may produce urethral obstruction, necessitating proximal urethrostomy. This will usually allow voiding in the upright position. With large lesions involving the penis, partial or total penectomy may be necessary. Radiation therapy and use of the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser to alleviate distal urethral obstruction have also been reported (Wishnow and Johnson, 1988; Ruszczak et al, 1996).

KEY POINTS: VIRUS-RELATED DERMATOLOGIC LESIONS

- HPV infection among men has been associated with penile carcinoma as well as with cervical dysplasia and carcinoma among female partners.
- Imiquimod cream has now become the standard topical treatment of choice for condyloma.
- Bowenoid papulosis, although appearing histologically similar to carcinoma in situ, occurs on the shaft of young men in most cases and does not progress to invasive disease.
- A diagnosis of penile Kaposi sarcoma is often associated with human herpesvirus 8 and should prompt an investigation into whether the patient is also infected with HIV or otherwise immunosuppressed.

Buschke-Löwenstein Tumor (Verrucous Carcinoma, Giant Condyloma Acuminatum)

The Buschke-Löwenstein tumor was initially described by Buschke and Löwenstein in 1925 and later by Löwenstein in 1939 in the United States. Ackerman (1948) described a histologically similar tumor occurring in the oral cavity. Verrucous carcinomas of the larynx, vulva, and penis were described by Goethals and colleagues (1963) (Fig. 37-1B).

The true incidence of the Buschke-Löwenstein tumor is unknown, but it is probably higher than reported because many cases have been labeled low-grade squamous carcinoma of the penis. Retrospective analyses of several reports have revealed a number of cases of verrucous cancer or giant condylomata under the category of low-grade squamous cell carcinomas (Davies, 1965; Hanash et al, 1970; Grussendorf-Conen, 1997).

The Buschke-Löwenstein tumor differs from condyloma acuminatum in that condylomata, regardless of size, always remain superficial and never invade adjacent tissue. Buschke-Löwenstein tumor displaces, invades, and destroys adjacent structures by compression. Aside from this unrestrained local growth, it demonstrates no signs of malignant change on histologic examination and does not metastasize. On microscopic examination, the tumor forms a luxuriant mass composed of broad rounded rete pegs, often extending far into underlying tissue. The pegs are composed of well-differentiated squamous cells that show no cellular anaplasia. These epithelial pegs are characteristically surrounded by a dense band of acute and chronic inflammatory cells. As with condyloma acuminatum, the cause may be viral (Dawson et al, 1965; Ubben et al, 1979; Antony et al, 2003). DNA from HPV types 6 and 11 has been identified in these tumors (Boshart and zur Hausen, 1986).

Lymph node metastases are rare with verrucous carcinoma (Ackerman, 1948; Davies, 1965; Seixas et al, 1994), and their presence probably reflects malignant degeneration in the primary lesion. Such changes are known to occur in verrucous carcinoma of nonpenile sites (Davies, 1965; Dawson et al, 1965). Anecdotal cases of malignant degeneration in association with penile carcinoma have been reported (Youngberg et al, 1983).

Either excisional biopsy or multiple deep biopsies are required to distinguish the lesion from true penile carcinoma. Treatment consists of excision, sparing as much of the penis as possible. Large lesions may necessitate total penectomy. Recurrence is common, and close follow-up is essential. Topical therapy with either podophyllin or 5-fluorouracil has been unsuccessful, probably because the characteristic thickened stratum corneum is impervious to the medication (Bruns et al, 1975).

Radiation therapy is ineffective for verrucous carcinoma (Lepor and Leffler, 1960; Kraus and Perez-Mesa, 1966; Proffitt et al, 1970; Fukunaga et al, 1994). Bleomycin has been used in both a primary and an adjunctive mode for verrucous carcinoma (Mishima and Matunaka, 1972). Successful treatment of a Buschke-Löwenstein tumor with systemic interferon therapy combined with Nd:YAG laser therapy has been reported (Gilbert and Beckert, 1990). Cryosurgery has also been employed with success (Michelman et al, 2002).

KEY POINTS: VERRUCOUS CARCINOMA

- Verrucous penile carcinoma exhibits progressive local growth but does not metastasize.
- It often requires surgical excision for definitive treatment.
- Treatment with radiation therapy is ineffective.

are considered, metastasis is extremely rare but has been reported (Eng et al, 1995).

Treatment is based on proper histopathologic confirmation of malignancy with multiple biopsies of adequate depth to rule out invasion. When lesions are located on the foreskin, circumcision or excision with a 5-mm margin is adequate for local control (Bissada, 1992). In this regard, lesions on the glans penis are more difficult to treat by excisional strategies while maintaining normal penile anatomy. Recently several groups have described the technique of glans resurfacing for penile squamous carcinoma of the glans penis. In this technique the epithelium and subepithelial tissue of the glans penis are completely dissected off the underlying spongiosal tissue. The resulting defect is then closed with a skin graft. Early follow-up reveals very low rates of local recurrence (Hadway et al, 2006; Shabbir et al, 2011b). Alternative strategies include topical 5-fluorouracil cream (Lewis and Bendl, 1971; Graham and Helwig, 1973; Goette, 1974), 5% imiquimod cream (Danielson et al, 2003), and ablation with Nd:YAG (Landthaler et al, 1986; Frimberger et al, 2002a), potassium titanyl phosphate (KTP) 532-nm, or carbon dioxide lasers (Rosemberg and Fuller, 1980; Tietjen and Malek, 1998; van Bezooijen et al, 2001). Such strategies have been shown to produce excellent cosmetic and functional results. Radiation therapy can be used to treat tumors that are resistant to topical treatment, especially among patients who are not surgical candidates (Kelley et al, 1974; Grabstald and Kelley, 1980; Mazoner et al, 1984; McLean et al, 1993).

KEY POINTS: CARCINOMA IN SITU

- Carcinoma in situ (Tis) is an intraepithelial malignant process.
- Progression to invasive carcinoma may occur in 5% to 33% of patients if it is not treated.
- Metastasis has rarely occurred.
- Cancer eradication with organ-preserving strategies is the goal of therapy.

Invasive Carcinoma

Penile carcinoma accounts for 0.4% to 0.6% of all malignant neoplasms among men in the United States and Europe; it may represent up to 10% of malignant neoplasms in men in some Asian, African, and South American countries (Gloeckler-Ries et al, 1990; Vatanasapt et al, 1995). However, reports suggest that the incidence of penile cancer is decreasing in many countries, including Finland, the United States, India, and other Asian countries (Maiche, 1992; Frisch et al, 1995; Vatanasapt et al, 1995; Yeole and Jussawalla, 1997). The reasons are unclear but may be related in part to increased attention to personal hygiene.

Penile cancer is a disease of older men, with an abrupt increase in incidence in the sixth decade of life (Persky, 1977). In two studies the mean ages were 58 years (Gursel et al, 1973) and 55 years (Derrick et al, 1973). The tumor is not unusual in younger men; in one large series, 22% of patients were younger than 40 years and 7% were younger than 30 years (Dean, 1935); the disease has also been reported in children (Kini, 1944; Narasimharao et al, 1985). The Surveillance, Epidemiology, and End Results (SEER) database reveals no racial difference in incidence of penile cancer between black and white men in the United States (incidence for white men, 0.8 per 100,000; for black men, 0.7 per 100,000) (Vatanasapt et al, 1995).

However, a study using SEER data suggested that race is associated with outcome. Rippentrop and colleagues (2004) noted there were 1605 patients diagnosed with penile cancer from 1973 to 1998, with 22.4% (360) dying of the disease. They found factors independently predictive of worsened survival to be higher stage at diagnosis, age older than 65 years, African-American ethnicity, and disease within lymph nodes. These researchers demonstrated a statistically significant disease-specific risk of death that was

2.2-fold higher in African-American patients than in white patients. Although the reason for this disparity is likely to be multifactorial, possibilities include differences in cancer biology, in health care access, or in treatment. These provocative findings clearly deserve further study.

Etiology

The incidence of carcinoma of the penis varies according to circumcision practice, hygienic standard, phimosis, number of sexual partners, HPV infection, exposure to tobacco products, and other factors (Barrasso et al, 1987; Maiche, 1992; Maden et al, 1993; Misra et al, 2004).

Neonatal circumcision has been well established as a prophylactic measure that virtually eliminates the occurrence of penile carcinoma because it eliminates the closed preputial environment where penile carcinoma develops. The chronic irritative effects of smegma, a byproduct of bacterial action on desquamated cells that are within the preputial sac, have been proposed as a causative agent. Although definitive evidence that human smegma itself is a carcinogen has not been established (Reddy and Baruah, 1963), its relationship to the development of penile carcinoma has been widely observed. Improper hygiene can lead to buildup of smegma beneath the preputial foreskin, with resulting inflammation. Healing by fibrosis leads to phimosis of the preputial skin, which tends to perpetuate the cycle. Phimosis is found in 25% to 75% of patients described in most large series. Reddy and associates (1984) studied the foreskins of 26 men undergoing circumcision because of phimosis and found epithelial atypia in one third of the specimens.

Carcinoma of the penis is rare among the Jewish population, for whom neonatal circumcision is a universal practice (Licklider, 1961). Similarly, in the United States, where neonatal circumcision is widely practiced, penile cancer represents less than 1% of male malignant neoplasms. Among noncircumcising tribes of Africa and within Asian cultures in which circumcision is not practiced, penile cancer may amount to 10% to 20% of all male malignant neoplasms (Dodge, 1965; Narayana et al, 1982). Data from most large series show that penile cancer is rare among neonatally circumcised individuals but more frequent when circumcision is delayed until puberty (Frew et al, 1967; Gursel et al, 1973; Johnson et al, 1973). Adult circumcision appears to offer little or no protection from subsequent development of the disease (Maden et al, 1993). These data suggest that the critical period of exposure to certain causative agents may have already occurred at puberty and certainly by adulthood, rendering later circumcision relatively ineffective as a prophylactic tool for penile cancer.

Population-based data reveal that although neonatal circumcision is highly protective for invasive penile cancer, it does not afford the same level of protection for carcinoma in situ. Schoen and colleagues (2000) evaluated the incidence of invasive penile cancer or carcinoma in situ during a 10-year period and found only 2 cases of 89 (2.3%) occurring among neonatally circumcised men, whereas of 118 men with carcinoma in situ, 16 cases were noted among 102 men who were circumcised at birth for an incidence of 15.7%. Considering that the protective effects of circumcision on invasive penile cancer are likely to be mediated by avoidance of phimosis, it is noteworthy that another study associated phimosis with the development of invasive penile cancer but not carcinoma in situ (Hung-fu et al, 2001).

Male circumcision has also been shown to be effective against HIV type 1 (HIV-1) infection. This effect was shown to be specific by Reynolds and colleagues (2004). There was no protective effect of circumcision for other sexually transmitted diseases, such as herpes simplex virus type 2 infection, syphilis, or gonorrhea.

HPV infection and exposure to tobacco products appear to be associated with development of penile cancer. Epidemiologic data provided the first clues to a relationship between a sexually transmitted agent and cancer by demonstrating that the wives or ex-wives of men with penile cancer had a threefold higher risk of cervical carcinoma (Graham et al, 1979). Further investigation revealed that

the male partners of women with cervical intraepithelial neoplasia had a significantly higher incidence of penile intraepithelial neoplasia (Barrasso et al, 1987). These same male patients were also found to have a greater incidence of HPV infection.

Polymerase chain reaction and *in situ* hybridization have provided increased evidence for a causative role of HPV by identifying specific DNA sequences from different HPV types in primary penile lesions (malignant and benign) but not in normal foreskins (Varma et al, 1991; Iwasawa et al, 1993). More than 25 types of HPV infect genital sites. HPV types 6 and 11 are most commonly associated with nondysplastic lesions such as genital warts, but these are also noted in nonmetastatic verrucous carcinomas. In contrast, HPV types 16, 18, 31, and 33 are associated with *in situ* and invasive carcinomas (Wiener and Walther, 1995). HPV-16 appears to be the most frequently detected type in primary carcinomas and has also been detected in metastatic lesions (Varma et al, 1991; Iwasawa et al, 1993; Wiener and Walther, 1995). As noted previously, the HPV genome encodes oncoprotein E6, which complexes with the tumor suppressor protein TP53, and oncoprotein E7, which binds the retinoblastoma (RB) protein, thus affecting cell cycle regulation (Munger et al, 1989; zur Hausen, 1996; Levi et al, 1998; Griffiths and Mellon, 1999) via the p14ARF/MDM2/p53 and p15INK4a/cyclin D/Rb pathways (Bleeker et al, 2009). Maden and colleagues (1993) found that the incidence of HPV infection directly correlated with the number of lifetime sexual partners, which was also related to risk of penile cancer. Furthermore, Castellsague and colleagues (1997) noted a direct correlation between the number of sexual partners, HPV-infected men, and incidence of cervical neoplasia among their female partners. Thus, for both cervical and penile cancer, HPV infection represents a preventable cause.

Poblet and coworkers (1999) reported on two patients with coexisting HIV-1 and HPV infection and postulated that HIV-1 could synergize with HPV to increase the progression of HPV penile lesions into penile carcinoma. Although there is evidence supporting this effect in cervical and anal neoplasia, definitive proof for penile cancer awaits further study (Northfelt, 1994).

Although HPV infection is probably an important factor in the development of penile cancer, its presence is not invariable (31% to 63% of patients with penile carcinoma test positive) (Wiener and Walther, 1995), indicating that additional factors may be involved in the development of the disease or its subtypes. Additional evidence includes a study by Rubin and associates (2001), who performed a sensitive polymerase chain reaction assay on penile cancer specimens from the United States and Paraguay and wrote their hypothesis-based essay. Overall, 42% of penile carcinomas were HPV positive. However, only 34.9% and 33.3% of keratinizing and verrucous carcinomas, respectively, were positive, whereas 80% and 100% of basaloid and warty tumor subtypes, respectively, exhibited HPV DNA. Other non-HPV-dependent molecular events leading to penile carcinogenesis have been described, including silencing of the CDK2NA locus via promoter hypermethylation, the expression of genes that target the INK4a/ARF locus, other gene mutations affecting TP53, and p14ARF, and MDM2 overexpression (reviewed in Ferreux et al, 2003; Bleeker et al, 2009).

Four studies have shown a significant association between exposure to cigarette smoke and development of penile cancer (Hellberg et al, 1987; Daling et al, 1992; Maden et al, 1993; Harish and Ravi, 1995). Hellberg and colleagues (1987) studied the smoking history of 244 men with penile cancer and matched controls. They found a significantly increased odds ratio for penile cancer based on whether an individual had smoked, and the risk increased with the number of cigarettes smoked. This observation held even when the presence of phimosis was controlled. Harish and Ravi (1995) extended these observations by showing that all forms of tobacco products, including cigarettes, chewing tobacco, and snuff, were significantly and independently related to the incidence of penile cancer subsequent to multivariate regression analysis. It has been hypothesized that tobacco products can act in the presence of HPV infection or bacteria associated with chronic inflammation to promote malignant transformation. These same risk factors are also

common to other anogenital carcinomas (Daling et al, 1992; Maden et al, 1993).

Penile trauma may be another risk factor for penile cancer. The development of carcinoma in the scarred penile shaft after mutilating circumcision has been reported as a distinct entity (Bissada et al, 1986). Furthermore, Maden and colleagues (1993) found a greater than threefold risk of penile cancer in men with penile tears and rashes. A case-control study also revealed an odds ratio of 18:1 for the development of penile cancer for those men reporting a penile injury 2 years before the onset of the disease (Hung-fu et al, 2001).

Genital ultraviolet radiation, alone and combined with 8-methoxypsoralen, increases the risk of squamous carcinoma at genital sites. A 12-year follow-up study reported that the risk of penile and scrotal cancer was increased 286 times that of the general population for those exposed to ultraviolet A photochemotherapy and 8-methoxypsoralen (PUVA) (Stern, 1990). The risk was dose related. For those treated with ultraviolet B exposure, the risk was 4.6-fold enhanced. Another long-term follow-up study of PUVA-associated malignant neoplasia from Sweden revealed a 30-fold increased risk for skin cancer (but not for penile cancer) among males. In this study, PUVA was also associated with respiratory and pancreatic cancers (Lindelof et al, 1991). Lichen sclerosus (also known as balanitis xerotica obliterans) is a risk factor for the development of penile cancer. Studies have shown the incidence of subsequent cancer with long-term follow-up to be between 2.3% and 9% of men with LS (Depasquale et al, 2000; Micali et al, 2001). Velazquez and Cubilla (2003) studied LS occurring in association with penile cancer and noted its presence distinctly among the subset of penile carcinomas that were not associated with HPV.

Larger studies performed in areas where the disease is endemic, incorporating the many risk factors for penile cancer into a multivariate analysis, are clearly needed to define which factors independently confer risk. Thus far, no convincing evidence has been found linking penile cancer to other factors such as occupation, other venereal diseases (gonorrhea, syphilis, and herpes), marijuana use, or alcohol intake (Maden et al, 1993).

Prevention

The role of routine neonatal circumcision as a preventive strategy for penile cancer has been, to say the least, a controversial topic. The position of the American Academy of Pediatrics has changed over time with accumulating evidence from one of denial of any medical benefits (Schoen et al, 1989) to the more moderate position stating, "There are potential medical benefits of newborn circumcision" (Shapiro, 1999) to the most recent statement published in August 2012, which states, "Evaluation of current evidence indicates that the health benefits of newborn male circumcision outweigh the risks and that the procedure's benefits justify access to this procedure for families who choose it." Specific benefits in their data review included prevention of urinary tract infections, penile cancer, and transmission of sexually transmitted infections including HIV (American Academy of Pediatrics Task Force on Circumcision, 2012).

Any argument against circumcision must consider that penile carcinoma represents the only neoplasm for which there exists a predictable and simple means of prophylaxis to spare the organ at risk (Dagher et al, 1973). Although circumcision can obviate the disease, especially where facilities for daily hygiene may be lacking, it may not be as important in countries where good hygiene is practiced. Frisch and colleagues (1995) reported a falling incidence of penile cancer (from 1.15 per 100,000 men to 0.82 per 100,000 men) in the Danish population, which has a circumcision rate of only 1.6%. They attributed this trend to improved hygiene because the incidence of dwellings having a bath facility increased from 35% in the 1940s to 90% in the 1990s. Thus, considering the benefits of circumcision (including the prevention of infections, HIV infection and its transmission, and penile and cervical cancer), enhanced education about the potential benefits of circumcision, especially in developing countries, seems rational (Schoen et al, 1989; Reynolds et al, 2004; Kinkade et al, 2005).

Although neonatal circumcision and good hygiene to prevent the occurrence of phimosis represent important prevention strategies, additional efforts to prevent malignant transformation include avoidance of HPV infection potentially through condom use, of ultraviolet light exposure, and of tobacco products. Thus, modifiable behaviors can potentially prevent penile cancer (Munger et al, 1989; Maden et al, 1993; Harish and Ravi, 1995; Levi et al, 1998; Griffiths and Mellon, 1999; Bleeker et al, 2009).

As mentioned previously, HPV vaccination could play an emerging role in the future with respect to preventing transmission of HPV between males and females and potentially penile cancer. To date two prophylactic HPV vaccines are available (HPV 16/18 vaccine Cervarix [GlaxoSmithKline] and the quadrivalent HPV 16/18/6/11 vaccine Gardasil [Merck Sharp & Dohme]), and the efficacy of preventing HPV infection among HPV-negative young women and men has been demonstrated (Harper et al, 2004; Villa et al, 2005; Block et al, 2006; Bleeker et al, 2009; Giuliano et al, 2011).

KEY POINTS: EPIDEMIOLOGY, ETIOLOGY, AND PREVENTION

- Penile cancer is rare in developed countries and varies worldwide with age, circumcision, and hygiene practices.
- Recent epidemiologic data from the United States suggest a disparity in outcome, with African-Americans exhibiting poorer survival.
- Risk factors for development of penile cancer include lack of neonatal circumcision, phimosis, HPV infection, exposure to tobacco products, penile LS, and potentially penile trauma and exposure to PUVA.
- Histologic subtypes of penile cancer are correlated with HPV infection.
- Penile cancer represents a preventable disease in most cases via neonatal circumcision and/or behavior modification.

Natural History

Carcinoma of the penis usually begins with a small lesion that gradually extends to involve the entire glans, shaft, and corpora. The lesion may be papillary and exophytic or flat and ulcerative; if it is untreated, penile autoamputation may occur as a late result. The rates of growth of the papillary and ulcerative lesions are similar, but the flat, ulcerative tumor has a tendency toward earlier nodal metastasis and is associated with poorer 5-year survival rates (Dean, 1935; Marcial et al, 1962; Ornellas et al, 1994). Lesions larger than 5 cm (Beggs and Spratt, 1964) and those extending over 75% of the shaft (Staubitz et al, 1955) are also associated with an increased incidence of metastases and a decreased survival rate. However, others have not found a consistent relationship among lesion sizes, presence of metastases, and decreased survival (Ekstrom and Edsmyr, 1958; Puras et al, 1978).

Buck fascia acts as a temporary natural barrier to local extension of the tumor, protecting the corporeal bodies from invasion. Penetration of Buck fascia and the tunica albuginea permits invasion of the vascular corpora and establishes the potential for vascular dissemination. Urethral or bladder involvement is rare (Riveros and Gorostiaga, 1962; Thomas and Small, 1968).

The earliest route of dissemination from penile carcinoma is metastasis to the regional femoral and iliac nodes. A detailed description of lymphatic drainage of the penis is found elsewhere in this text and is well documented in the literature (Dewire and Lepor, 1992). Briefly, the lymphatics of the prepuce form a connecting network that joins with the lymphatics from the skin of the shaft. These tributaries drain into the superficial inguinal nodes (the nodes external to the fascia lata). The lymphatics of the glans join

the lymphatics draining the corporeal bodies, and they form a collar of connecting channels at the base of the penis that drain by way of the superficial nodes. The superficial nodes drain to the deep inguinal nodes (those deep to the fascia lata). From there, drainage is to the pelvic nodes (external iliac, internal iliac, and obturator). Penile lymphangiographic studies demonstrate a consistent pattern of drainage that proceeds from superficial inguinal to deep inguinal to pelvic node sites without evidence of ipsilateral drainage (Cabanias, 1977, 1992). Multiple cross-connections exist at all levels of drainage, so that penile lymphatic drainage is bilateral to both inguinal areas.

Metastatic enlargement of the regional nodes eventually leads to skin necrosis, chronic infection, and death from inanition, sepsis, or hemorrhage secondary to erosion into the femoral vessels. Clinically detectable distant metastatic lesions to the lung, liver, bone, or brain are uncommon and are reported to occur in 1% to 10% of patients in most large series (Staubitz et al, 1955; Riveros and Gorostiaga, 1962; Beggs and Spratt, 1964; Derrick et al, 1973; Johnson et al, 1973; Kossow et al, 1973; Puras et al, 1978, reviewed in Pettaway et al, 2010). Such metastases usually occur late in the course of the disease after the local lesion has been treated. Distant metastases in the absence of regional node metastases are unusual.

Carcinoma of the penis is characterized by a relentless progressive course, causing death for the majority of untreated patients within 2 years (Beggs and Spratt, 1964; Skinner et al, 1972; Derrick et al, 1973). Rarely, long-term survival occurs, even with advanced local disease and regional node metastases (Furlong and Uhle, 1953; Beggs and Spratt, 1964). No report of spontaneous remission of carcinoma of the penis is known. Five percent to 15% of patients have been reported to develop a second primary neoplasm (Buddington et al, 1963; Beggs and Spratt, 1964; Gursel et al, 1973), and one series reported secondary carcinoma in 17% of patients (Hubbell et al, 1988).

Modes of Presentation

Signs

It is the penile lesion itself that usually alerts the patient to the presence of penile cancer. The presentation ranges from a relatively subtle induration or small excrescence to a small papule, pustule, warty growth, or more luxuriant exophytic lesion. It may appear as a shallow erosion or as a deeply excavated ulcer with elevated or rolled-in edges. Phimosis may obscure a lesion and allow a tumor to progress silently. Eventually, erosion through the prepuce, foul preputial odor, and discharge with or without bleeding call attention to the disease.

Penile tumors may arise anywhere on the penis but occur most commonly on the glans (48%) and prepuce (21%). Other tumors involve the glans and prepuce (9%), the coronal sulcus (6%), or the shaft (<2%) (Sufrin and Huben, 1991). This distribution of lesions may be the result of constant exposure of the glans, coronal sulcus, and interior prepuce to irritants (e.g., smegma, HPV infection) within the preputial sac, whereas the shaft is relatively spared.

Rarely, a mass, ulceration, suppuration, or hemorrhage in the inguinal area may be caused by nodal metastases from a lesion concealed within a phimotic foreskin. Urinary retention or urethral fistula from local corporeal involvement is a rare presenting sign.

Symptoms

Pain does not develop in proportion to the extent of the local destructive process and usually is not a presenting complaint. Weakness, weight loss, fatigue, and systemic malaise occur secondary to chronic suppuration. On occasion, significant blood loss from the penile lesion, the nodal lesion, or both may occur. Because local disease and regional disease are usually far advanced by the time distant metastases occur, presenting symptoms referable to such metastases are rare.

Diagnosis

Delay

Patients with cancer of the penis, more than patients with other types of cancer, seem to delay seeking medical attention (Lynch and Krush, 1969). In large series, 15% to 50% of patients delayed medical care for more than a year (Dean, 1935; Buddington et al, 1963; Hardner et al, 1972; Gursel et al, 1973). Explanations include embarrassment, guilt, fear, ignorance, and personal neglect. This level of denial is substantial, given that the penis is observed and handled on a daily basis.

Delay on the part of the physician in initiating both diagnosis and treatment may also be considerable. In some instances patients have been given prolonged courses of antibiotics or topical antifungal preparations before being referred for biopsy. Although some studies show that the difference in survival rates between patients with early presentation and those with later presentation is negligible (Ekstrom and Edsmyr, 1958; Johnson et al, 1973), other series show decreased survival with longer delay (Hardner et al, 1972). It appears logical that earlier diagnosis and treatment should improve outcome.

Examination

At presentation most lesions are confined to the penis (Skinner et al, 1972; Derrick et al, 1973; Johnson et al, 1973). The penile lesion is assessed with regard to size, location, fixation, and involvement of the corporeal bodies. Inspection of the base of the penis and scrotum is necessary to rule out extension into these areas. Rectal and bimanual examination provides information about perineal body involvement and presence of a pelvic mass. Careful bilateral palpation of the inguinal area for adenopathy is extremely important.

KEY POINTS: NATURAL HISTORY AND PRESENTATION

- Penile cancer often begins on the surface of the glans penis or in the preputial area, where it progressively enlarges.
- Delay both in seeking medical attention and then in subsequent definitive biopsy is common.
- Examination of both the penile primary tumor and the inguinal region is critical to treatment planning.
- Metastasis occurs by embolization of tumor deposits from the penile tumor through penile lymphatics to the inguinal lymph nodes.
- Distant metastases occur late in the history of the disease.

Biopsy

Confirmation of the diagnosis of carcinoma of the penis and assessment of the depth of invasion, the presence of vascular invasion, and the histologic grade of the lesion by microscopic examination of a biopsy specimen are mandatory before the initiation of any therapy. This provides insight into the therapeutic options for treatment of the primary lesion as well as the likelihood of nodal metastases in patients with no palpable adenopathy (McDougal, 1995; Lopes et al, 1996; Theodorescu et al, 1996).

Biopsy may be a separate procedure from definitive surgical treatment. A dorsal slit is frequently necessary to gain adequate exposure of the lesion for satisfactory biopsy. An alternative approach to treatment is biopsy with frozen-section confirmation followed by partial or total penectomy. Full informed consent must be obtained before the procedure. Velazquez and colleagues (2004) demonstrated the shortcomings of superficial diagnostic biopsies in a study evaluating specimens from 57 patients. There was difficulty in delineating the extent of depth in 91% of patients, discordance with the histologic grade in 30% of patients (specifically with

verrucous and mixed histologic patterns), and failure to detect any cancer in 3.5% of patients with well-differentiated cancers. The importance of obtaining an adequate biopsy specimen cannot be overemphasized.

Histologic Features

Most tumors of the penis are squamous cell carcinomas demonstrating keratinization, epithelial pearl formation, and various degrees of mitotic activity. The normal rete pegs are disrupted. Invasive lesions penetrate the basement membrane and the surrounding structures. Cubilla and associates (1993) originally divided penile cancers by growth pattern into superficially spreading squamous carcinoma, vertical growth carcinoma, verrucous carcinoma, and multicentric carcinoma. The superficially spreading carcinoma occurred most frequently, and inguinal lymph node metastases were found in 42% of patients. However, lymph node metastases were noted in 82% of patients with a vertical growth pattern, in none of those with a verrucous pattern, and in 33% of those with multicentric carcinomas. Subsequent to review of 61 cases from Memorial Sloan Kettering Cancer Center, Cubilla and colleagues (2001) classified the histologic types as follows: usual type, 59% of cases; papillary, 15%; basaloid, 10%; warty (condylomatous), 10%; verrucous, 3%; and sarcomatoid, 3%. Of note, both the basaloid and sarcomatous types were associated with aggressive behavior; 5 of 7 patients with these histologic patterns exhibited metastasis, and 5 of 8 (63%) died. In contrast, the verruciform histologic patterns were more favorable (1 patient with metastasis and no deaths). The typical squamous histologic type was intermediate in biologic potential; 14 of 26 patients exhibited metastases, and 13 of 36 (36%) died.

The basaloid variant, in addition to its aggressive behavior as noted previously, is associated with HPV expression in approximately 80% of cases (Gregoire et al, 1995; Cubilla et al, 1998, 2001; Rubin et al, 2001).

Squamous cell carcinomas have classically been graded using the Broders classification to define the level of differentiation on the basis of keratinization, nuclear pleomorphism, number of mitoses, and several other features (Broders, 1921; Lucia and Miller, 1992). This grading system was originally designed for squamous carcinoma of the skin and has been adapted by pathologists for penile squamous carcinoma. Four grades were originally described, but it is common for authors to modify this to a three-grade system by combining grades (Maiche et al, 1991). Low-grade lesions (grade 1 and grade 2) constitute 70% to 80% of the reported cases at diagnosis, whether a three- or four-grade system is used (Maiche et al, 1991). These well-differentiated lesions show cords of atypical squamous cells projecting downward from a hyperkeratotic epidermis. The lower-grade carcinomas typically demonstrate keratin, prominent intercellular bridges, and keratin pearls, characteristics that are absent in high-grade tumors. Almost half the tumors originating in the shaft are poorly differentiated (grade 3 and grade 4, depending on scale), whereas only 10% of tumors located in the prepuce are high-grade tumors (Maiche et al, 1991). Thus, grade and stage are often correlated.

Several studies have emphasized the association of high-grade disease with regional nodal metastases (Fraleigh et al, 1989; Ravi, 1993a; McDougal, 1995; Theodorescu et al, 1996; Heyns et al, 1997). Overall, there is a significant body of agreement as to the histologic features that characterize high tumor grade (grade 3 and grade 4) and its correlation with nodal metastasis. However, as noted previously, most tumors are of lower grades. Histologic features that would better stratify the prognosis for patients with invasive, low- to intermediate-grade penile cancers would be of value for management of patients.

Slaton and colleagues (2001) found that describing the percentage of poorly differentiated cancer in the primary penile tumor specimen correlated with lymph node metastasis. In this study, a semiquantitative system that estimated the amount of high-grade cancer (i.e., $\leq 50\%$ vs. $>50\%$) was significantly associated with nodal metastases and was more predictive than the Broders

three-grade system in stratifying those with or without nodal metastasis.

However, [Chaux and colleagues \(2009\)](#) questioned these findings as they examined 117 specimens among patients undergoing primary tumor therapy and lymph node dissection. Over 50% of the tumors were actually heterogeneous with respect to grade, and among these tumors any proportion of grade 3 cancer was associated with lymph node metastasis. These disparate findings point to at least three problems with respect to grading and prognosis, including (1) lack of a uniform system, (2) reproducibility of interpretation, and (3) intratumoral heterogeneity of tumor components.

Vascular invasion by tumor cells has significant prognostic importance but may not be specifically mentioned in pathology reports. When vascular invasion is present, it provides valuable information. Four studies have assessed its presence or absence, and it was an important predictor of nodal metastasis in all the reports ([Fraleigh et al, 1989](#); [Lopes et al, 1996](#); [Heyns et al, 1997](#); [Slaton et al, 2001](#)). Thus the pathologist should specifically comment on the presence or absence of vascular invasion in the surgical specimen.

Perineural invasion was recently found to be present in 36% of cases analyzed in a multi-institutional data set of 134 patients and was a strong predictor of lymph node metastasis ([Velazquez et al, 2008](#)).

KEY POINTS: BIOPSY AND HISTOLOGIC FEATURES

- Adequate tumor biopsy is essential to diagnosis and treatment planning.
- Squamous carcinoma histologic subtypes include usual type, papillary, basaloid, warty, verrucous, and sarcomatoid. They vary with respect to metastatic potential.
- Pathologic description of anatomic structures invaded (i.e., stage), the grade, and the status of vascular and perineural invasion provide important information to assess the risk of metastasis.

Laboratory Studies

The results of laboratory tests in patients with penile cancer are often normal. Anemia, leukocytosis, and hypoalbuminemia may be present in patients with chronic illness, malnutrition, and extensive suppuration at the area of the primary and inguinal metastatic sites. Azotemia may develop secondary to urethral or ureteral obstruction.

Hypercalcemia without detectable osseous metastases has been associated with penile cancer ([Anderson and Glenn, 1965](#); [Rudd et al, 1972](#)). In a review from Memorial Sloan Kettering Cancer Center ([Sklaroff and Yagoda, 1982](#)), 17 of 81 patients (20.9%) were hypercalcemic. Hypercalcemia seems to be largely a function of the bulk of the disease. It is often associated with inguinal metastases and may resolve after excision of involved inguinal nodes ([Block et al, 1973](#)). **Parathyroid hormone and related substances may be produced by both tumor and metastases that activate osteoclastic bone resorption** ([Malakoff and Schmidt, 1975](#)). Medical treatment of hypercalcemia includes aggressive saline hydration to restore the extracellular fluid volume and to promote both sodium and calcium excretion. The administration of diuretics is performed if volume overload is suspected. Bisphosphonates (e.g., pamidronate, etidronate, and zoledronic acid) have become first-line therapy because they possess demonstrated efficacy as antiresorptive agents and are relatively safer than mithramycin, an older agent ([Videtic et al, 1997](#); [Morton and Lipton, 2000](#)). For severe hypercalcemia associated with neurologic manifestations, the antiresorptive bisphosphonates can be combined with an

agent that produces calciuria, such as calcitonin, to rapidly lower serum calcium levels.

Radiologic Studies

Primary Penile Tumor. In patients with penile cancer both the primary tumor and the inguinal lymph nodes are readily assessed by palpation. However, [Horenblas and associates \(1991\)](#) found that physical examination incorrectly established the actual pathologic stage in 26% of cases, with understaging in 10% and overstaging in 16%. It is clear that more accurate means of staging for penile tumors is needed.

Penile ultrasonography was performed on 16 patients referred for primary therapy by [Horenblas and colleagues \(1994\)](#). With use of a 7.5-MHz linear array small parts transducer they found that the ultrasound appearance of cancer was invariably hypoechoic. However, ultrasound examination often underestimated the thickness of tumors and could not delineate invasion into the subepithelial connective tissue of the glans penis from corpus spongiosum involvement (i.e., glanular stage T1 vs. glanular stage T2). However, the tunica albuginea separating the corpus cavernosum from the glans was easily identified in all patients, and the sensitivity for detecting corpus cavernosum invasion was 100%. This study confirmed the value of ultrasonography in assessing the primary tumor, as reported by others ([Yamashita and Ogawa, 1989](#); [Dorak et al, 1992](#)).

Several studies have assessed the role of magnetic resonance imaging (MRI) in evaluating both the normal penis and its involvement by cancer. [Vapnek and associates \(1992\)](#) described the MRI appearance of the normal corpus cavernosum, corpus spongiosum, tunica albuginea, and Buck fascia. Of six patients with urethral cancer, the disease was accurately staged in five (83%). [De Kerviler and colleagues \(1995\)](#) used gadolinium contrast-enhanced MRI to compare both clinical and MRI findings with tumor pathologic stage. Clinical examination correctly staged six of nine tumors: MRI was correct in seven of nine cases but was not useful for clinical T1 lesions. Compared with MRI and ultrasonography, computed tomography (CT) has poor soft-tissue resolution and has not been useful for imaging the extent of the primary tumor ([Vapnek et al, 1992](#)).

[Lont and associates \(2003\)](#) directly compared physical examination with ultrasonography and MRI to assess their ability to determine the tumor stage. They evaluated 33 patients with penile squamous cell carcinoma, all of whom underwent ultrasound examination, MRI, and physical examination of the primary tumor. Findings were correlated with histologic evaluation of the specimens obtained at surgery with a focus on determining the invasion of the corpus cavernosum. The respective positive predictive value, sensitivity, and specificity for the study were as follows—physical examination: 100%, 86%, 100%; ultrasound examination: 67%, 57%, 91%; and MRI: 75%, 100%, 91%. This comparative study concluded that physical examination is reliable in determining corporeal invasion and that additional tests are mainly of value when physical examination cannot be properly performed.

The technique of artificial erection (by intracorporeal injection of prostaglandin E₁) may augment the use of contrast-enhanced MRI in staging of the primary tumor. A study by the European Institute of Oncology evaluated nine patients to compare clinical, pathologic, and MRI staging ([Scardino et al, 2004](#)). MRI aided by artificial erection and contrast enhancement was shown to be of value because it correlated with pathologic stage in eight of nine cases, whereas physical examination correlated with only five of nine cases. These data suggest that this novel MRI approach could be beneficial in staging of glanular tumors, specifically when physical examination findings are equivocal. Thus, for small-volume glanular lesions, imaging studies add virtually no additional information to palpation in most patients. However, for lesions thought to invade the corpus cavernosum, contrast-enhanced MRI (perhaps augmented with artificial erection) may provide unique information, especially when physical examination

findings are equivocal and organ-sparing techniques are being considered.

Inguinal and Pelvic Region

Current Imaging Strategies among Clinical Node-Negative Patients. The ability to noninvasively determine the presence or absence of inguinal and pelvic metastases in patients with penile cancer remains problematic because physical examination exhibits varying reliability based on the grade and stage of the primary tumor as well as body habitus of the patient. Both CT and MRI techniques have depended on lymph node enlargement for detection of metastases but are unable to define the internal architecture of normal-sized nodes. Because CT and MRI have similar accuracy in determining lymphadenopathy in other cancers, CT has often been the imaging modality chosen in penile cancer to examine the inguinal and pelvic areas as well as to rule out more distant metastases.

Horenblas and associates (1991) compared the ability of physical examination, CT, and lymphangiography to assess the inguinal region in patients who were surgically staged or had prolonged follow-up. In 102 patients with a 39% prevalence of positive nodes, the sensitivity and specificity of physical examination were 82% and 79%, respectively. Of note, both CT and lymphangiography were performed in patients who were thought to have metastases. The sensitivity of lymphangiography was only 31%, but there were no false-positive results. Similarly, the sensitivity and specificity of CT were 36% and 100%, respectively. The combination of CT and lymphangiography performed simultaneously demonstrated equally poor sensitivity. Only one fifth of patients had positive nodes detected with either test. On the basis of these data the authors concluded that CT and lymphangiography offer no useful additional information over physical examination, especially in patients with no palpable adenopathy. An important caveat is that CT may have a role in examination of the inguinal region in obese patients or in those who have had prior inguinal surgery, in whom the physical examination may be unreliable.

Insights in the field of nanoparticle technology have been applied to imaging of genitourinary malignant neoplasms to enhance detection of microscopic metastases. Ferumoxtran-10 particles (size, 35 nm), administered at a dose of 2.6 mg of iron per kilogram of body weight intravenously combined with MRI, were capable of imaging microscopic metastasis in lymph nodes that were by size criteria normal (1 cm). Tabatabaei and colleagues (2005) evaluated lymphotropic nanoparticle-enhanced MRI (LNMRI) in seven patients with penile cancer who subsequently underwent groin dissection. Five of seven patients had no palpable adenopathy. LNMRI was highly sensitive and detected positive nodes in all five of these patients. Of note, the size range of the metastases was less than 1 cm in four patients. Unfortunately, no confirmatory studies were performed using this agent, and the compound is not currently available for routine use.

Squamous carcinoma was shown to take up the radiopharmaceutical fluorodeoxyglucose (FDG) and to be amenable to detection using combination positron emission tomography (PET) and CT. Scher and associates (2005) evaluated PET/CT among 13 patients with penile cancer who received injections of FDG. Five of the 13 patients had metastatic disease, and FDG-PET/CT detected it in 4 of them (80% sensitivity). However, in a follow-up study from the Netherlands, PET/CT was used in patients who were clinically node negative to determine the sensitivity among patients scheduled to undergo inguinal staging procedures. Among 5 patients with proven nodal metastasis, PET/CT was positive in only 1 (i.e., sensitivity of 20%) (Leijte et al, 2009a).

Among a similar cohort reported from this same group, ultrasound-guided needle aspiration was also shown to have limited sensitivity as well, detecting only 9 of 23 patients with proven metastases (sensitivity of 39%; Kroon et al, 2005a). Thus, among clinically node-negative patients, no current imaging modality has been shown to be sufficiently sensitive to detect microscopic metastases.

Current Imaging Strategies among Clinical Node-Positive Patients. Recent data among patients with proven inguinal

metastases suggest that additional imaging may be of value in determining those patients with advanced disease who might do poorly when treated with surgery alone or could in fact exhibit occult distant metastases.

Graafland and colleagues (2011) evaluated the CT scan findings among a cohort of biopsy-proven patients with metastatic inguinal adenopathy to define if scan parameters could determine those with poor prognostic features subsequent to lymphadenectomy. They found that central necrosis or an irregular nodal border was highly sensitive and specific for any of the poor prognostic features including three or more positive nodes, extranodal extension (ENE) of cancer, or positive pelvic nodes.

In contrast to the clinically node-negative disease setting, one study has shown the potential value of PET/CT among patients with proven inguinal metastases. Graafland and coworkers (2009) studied PET/CT among 18 patients with biopsy-proven inguinal metastases and found PET/CT to have a sensitivity and specificity of 91% and 100%, respectively, for detecting pelvic lymph node metastases. In that study, PET/CT also identified several patients with distant metastases that were unsuspected. Thus, if confirmed, PET/CT may become an important study for detecting pelvic and distant metastasis.

In general, distant metastases occur late in the course of the disease, usually in patients with recognized significant inguinal and pelvic adenopathy. The most common metastatic sites are the lung, bone, and liver. Currently, in addition to chest, abdominal, and pelvic CT, radionuclide bone scintigraphy may be indicated to stage the extent of disease in patients thought to have widespread metastases (Vapnek et al, 1992).

KEY POINTS: RADIOLOGIC STUDIES

- Soft-tissue detail of penile tumors is best imaged by MRI.
- Physical examination provides the most reliable staging information for small distal lesions.
- Penile MRI performed in combination with artificial erection may provide unique staging information when physical examination findings are equivocal.
- Physical examination of the inguinal region remains the clinical gold standard for evaluating the presence of metastasis in the nonobese patient.
- CT or MRI can be useful in evaluating the inguinal region of obese patients and in those who have had prior inguinal surgery.
- Among patients with proven inguinal metastases, CT scan of the abdomen and pelvis may help to determine those patients with poor prognostic features for cure with surgery alone.
- PET/CT may be useful among patients with clinically detected inguinal metastases to define the presence of pelvic or distant metastasis.

Penile Cancer Staging

Seventh Edition TNM Penile Staging System. The seventh edition of the American Joint Committee on Cancer (AJCC) and Union for International Cancer Control (UICC) TNM staging system was published in 2010 and has become the consensus method for staging penile cancer (Table 37-1, Fig. 37-2) (Edge et al, 2010). With respect to the primary tumor, because grade and the presence of vascular invasion are established prognostic markers in predicting the risk of subsequent inguinal metastasis, the seventh edition TNM stratifies pT1 stage by their presence (i.e., high-grade tumors, vascular invasion present is pT1b) or absence (pT1a) (Slaton et al, 2001; Solsona et al, 2004; Ficarra et al, 2005). In addition, prostatic invasion (a rare finding) is now included in the pT4 designation.

Of considerable importance is that the seventh edition has both clinical and pathologic nodal staging descriptors to facilitate both

TABLE 37-1 American Joint Committee on Cancer (AJCC) Staging for Penile Cancer

PRIMARY TUMOR (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ		
Ta	Noninvasive verrucous carcinoma*		
T1a	Tumor invades subepithelial connective tissue without lymphovascular invasion and is not poorly differentiated (i.e., grade 3-4)		
T1b	Tumor invades subepithelial connective tissue with lymphovascular invasion or is poorly differentiated		
T2	Tumor invades corpus spongiosum or cavernosum		
T3	Tumor invades urethra		
T4	Tumor invades other adjacent structures		
LYMPH NODES (N)			
NX	Regional nodes cannot be assessed†		
pNX	Regional nodes cannot be assessed‡		
N0	No palpable or visibly enlarged inguinal lymph nodes†		
pN0	No regional lymph node metastasis‡		
N1	Palpable mobile unilateral inguinal lymph node†		
pN1	Metastasis in a single inguinal lymph node‡		
N2	Palpable mobile multiple or bilateral inguinal lymph nodes†		
pN2	Metastasis in multiple or bilateral inguinal lymph nodes‡		
N3	Palpable fixed inguinal nodal mass or pelvic lymphadenopathy, unilateral or bilateral†		
pN3	Extranodal extension of lymph node metastasis or pelvic lymph node(s), unilateral or bilateral‡		
DISTANT METASTASIS (M)

clinical and pathologic staging to better predict prognosis before definitive therapy. As pointed out by [Leijte and colleagues \(2008\)](#), the prognosis worsens for patients exhibiting greater degrees of palpable adenopathy (i.e., unilateral vs. bilateral vs. a fixed mass) or positive nodes on imaging versus those with clinically negative inguinal lymph nodes. Considering pathologic nodal factors further,

the seventh edition stratifies patients with a single positive node from those with multiple or bilateral nodes and further recognizes the ominous prognosis (5% to 18% 5-year survival) associated with ENE of cancer ([Srinivas et al, 1987](#); [Ravi, 1993a](#); [Lont et al, 2007](#)).

Considering that the pathologic status of inguinal nodes is the driving factor determining survival, stage groupings (i.e., stage 0 to

Figure 37-2. Because treatment decisions for inguinal node dissections are based on the characteristics of the primary lesion (see section on [treatment of inguinal nodes](#)), a careful assessment of the depth of invasion of the primary tumor is required. This diagram illustrates the importance of depth of invasion in assigning tumor (T) stage.

stage IV [see [Table 37-1](#)]) in the seventh edition TNM use the extent of nodal involvement as the major consideration. Thus the strength of the unified AJCC-UICC seventh edition TNM system (2010) is that it provides not only an accurate assessment of the primary tumor based on clinical staging (examination, biopsy) but also clinical and improved pathologic descriptors of lymph node status to predict outcome. Furthermore, the nodal status of the new TNM version has been externally validated among node-positive patients in a recent study from Shanghai ([Zhu et al, 2011](#)). In that study, stratification of recurrence-free survival among N1 to N3 categories was significantly better when comparing the seventh edition TNM to the prior sixth edition system.

Another recent important prognostic variable, lymph node density (LND), has been described. This variable describes the number of positive inguinal or pelvic nodes removed at surgery as a function of the total number of nodes removed. Thus, in addition to describing the number of positive lymph nodes, it also includes a potential quality variable in incorporating the total lymph node yield. [Svatek and colleagues \(2009\)](#) described this initially in a small series of 45 patients with proven inguinal metastasis, finding that LND was the strongest predictor of disease-specific survival, even when considering TNM stage and extracapsular extension. [Zhu and colleagues \(2011\)](#) confirmed this finding subsequently and also showed that LND retained its independent prognostic ability even when considering the improved seventh edition TNM staging system. Larger series of node-positive patients will be required to more precisely determine clinically useful cutoff values for LND as well as what constitutes an adequate lymph node yield at lymphadenectomy.

In the TNM staging system the primary tumor stage is assigned by biopsy (or even more reliably by complete resection) and

BOX 37-1 Minimal Diagnostic Criteria for Carcinoma of the Penis

PRIMARY TUMOR (T)

Clinical examination

Incisional-excisional biopsy of lesion (or complete resection) and histologic examination for grade, anatomic structure invaded, and presence of vascular invasion

REGIONAL AND JUXTAREGIONAL LYMPH NODES (N)

Clinical examination

CT, if inguinal adenopathy is palpable*

CT/PET may be considered for bulky inguinal adenopathy†

Superficial inguinal node dissection or dynamic sentinel node biopsy (as indicated for high grade, vascular invasion, or invasive histologic pattern)

Aspiration cytology (as indicated)

DISTANT METASTASES (M)

Clinical examination

Biochemical determinations (liver functions, calcium)

CT scan of the chest, abdomen, pelvis; bone scintigraphy; or CT/PET scan (as indicated)

*CT should also be performed in obese patients and those who have had prior inguinal surgery, whose physical examination findings may be unreliable.

†CT/PET scans coregistered to correlate uptake with anatomic location. CT, computed tomography; PET, positron emission tomography.

additional prognostic factors within the primary tumor now included in the TNM system (i.e., tumor grade and the presence of vascular invasion). In most cases the presence of palpable adenopathy, along with the histologic features of the primary tumor, determines the need for additional imaging studies. Positive fine-needle aspiration of palpably enlarged inguinal nodes or fine-needle biopsy of pelvic adenopathy identified by CT can assist in assigning nodal stage before therapy. In patients requiring surgical staging (palpable lymph nodes or those with adverse primary tumor histologic features), pathologic nodal status assigned according to seventh edition TNM stage provides valuable prognostic information. The suggested diagnostic criteria for current TNM staging are listed in [Box 37-1](#).

KEY POINTS: STAGING

- Both clinical and pathologic factors related to the presence and extent of lymph node involvement determine survival and should be recorded.
- The current, seventh edition unified TNM staging system represents a consensus document that includes both clinical and pathologic descriptors that provide important prognostic information.

Differential Diagnosis

A number of penile lesions must be considered in the differential diagnosis of penile carcinoma. They include condyloma acuminatum, Buschke-Löwenstein tumor, and balanitis xerotica obliterans, as well as a number of infectious lesions (e.g., chancre, chancroid, herpes, lymphopathia venereum, granuloma inguinale, and tuberculosis). These diseases can be identified by appropriate skin tests, tissue studies, serologic examinations, cultures, or specialized staining techniques.

SURGICAL MANAGEMENT OF THE PRIMARY TUMOR

Organ Preservation

Surgical amputation of the primary tumor remains the oncologic gold standard for rapid definitive treatment of the penile primary tumor; local recurrence rates range from 0% to 8% (de Kernion et al, 1973; McDougal et al, 1986; Horenblas et al, 1992). Whereas amputation is often necessary for bulky stage T2 to T4 tumors, it has been shown to decrease sexual quality of life (Opjordsmoen and Fossa, 1994). This is relevant because approximately 55% of penile cancer patients are 60 years of age or younger and 30% are 55 years of age or younger (Narayana et al, 1982).

It is generally accepted that patients with penile primary tumors exhibiting favorable histologic features (stages Tis, Ta, T1; grade 1 and grade 2 tumors) are at a lower risk for metastases. These patients are also best suited for organ-sparing or glans-sparing procedures (Solsona et al, 2004). The goal of treatment is to preserve glans sensation where possible or at least to maximize penile shaft length. Such approaches include topical treatments (5-fluorouracil or imiquimod cream for Tis only), radiation therapy, Mohs surgery, limited excision strategies, and laser ablation (Sanchez-Ortiz and Pettaway, 2003; Solsona et al, 2004; Minhas et al, 2005; Crook et al, 2009; Alnajjar et al, 2012). This section focuses on novel insights into surgical strategies to achieve organ preservation. Radiation-based strategies are discussed later in the section on radiation therapy for the primary lesion.

Circumcision and Limited Excision Strategies

Circumcision, limited excisions of the glans, and glans removal with sparing of the penile shaft represent surgical strategies to maintain function and penile length. Historically, data on circumcision and limited excision of glanular lesions have been associated with recurrence rates from 11% to 50% (Hanash et al, 1970; Skinner et al, 1972; McDougal et al, 1986). However, the grade, size, and exact location of the lesion and the status of surgical margins were often unavailable in such reports.

Recent reports have suggested that conservative surgery may be performed safely in well-selected patients with discrete tumors by intraoperative frozen-section analysis (Davis et al, 1999; Bissada et al, 2003; Pietrzak et al, 2004; Minhas et al, 2005). In addition, several studies have challenged the dictum establishing that a 2-cm surgical margin is required for all patients undergoing partial penectomy (Hoffman et al, 1999; Agrawal et al, 2000). After performing a prospective histologic analysis of 64 penectomy specimens, Agrawal and associates (2000) concluded that tumor grade highly correlated with microscopic tumor spread. The maximum proximal histologic extent was 5 mm for grade 1 and grade 2 tumors and 10 mm for grade 3 tumors. Furthermore, "skip" lesions were not encountered. After performing a retrospective pathologic review of 12 penectomy specimens, Hoffman and colleagues (1999) also found 7 patients with disease of pathologic stage T1 or greater with microscopic margins measuring less than 10 mm. None of these patients had disease recurrence at a mean follow-up of 32.4 months. Pietrzak and colleagues (2004) documented the use of various techniques in a series of 39 patients to excise the tumor and to reconstruct or graft the glans and distal penis. With a mean follow-up of 16 months, only 1 patient (2.5%) who underwent a partial glans resection had a local recurrence. There were two early complications with grafts and two late complications with graft overgrowth intruding on the urethral meatus. Minhas and associates (2005) similarly performed either wide local excision or glans penis removal in 51 patients with margins of 0 to 10 mm in 48% and less than 2 cm in 98% of patients. With a median follow-up of 26 months, a local recurrence rate of 4% to 6% was noted. Limitations of this approach include proximal and distal deeply invasive tumors, high-grade tumors, and patients with poor health status who would not be candidates for salvage procedures if they experienced recurrence. A follow-up series from this same group that included 179 patients having undergone a variety

of organ-sparing procedures including glansectomy, excisions, and distal corporectomy was recently reported (Philippou et al, 2012). With a mean follow-up of 43 months, the incidence of recurrence was 8.9% (16 patients). It is important to note that local relapse did not affect disease-specific survival. These results seem to suggest that a 2-cm margin may not be necessary for small tumors of lower grade in the presence of a negative frozen section. However, patients managed with limited excision techniques should be considered to be at a higher risk for local recurrence until longer-term follow-up and additional surgical series are available.

Another recent technique used in the surgical management of carcinoma in situ of the glans penis is *glans resurfacing*, also known as *glans stripping*. In this technique, subdermal dissection of the skin and subepithelial connective tissue off the underlying corpora spongiosa is performed. Shabbir and colleagues (2011a) described this procedure in 25 patients with clinical carcinoma in situ of the glans; they performed either a total or partial removal of all the glans surface tissue. Positive surgical margins were noted in 48% of patients overall but in only 20% of those having total removal. At a mean of 29 months, 5 patients underwent re-excision for unexpected invasive disease at the margin. One of 25 patients exhibited a clinical recurrence. Topical therapy was used for isolated positive margins with carcinoma in situ. Important considerations for this procedure are to document the absence of invasive cancer, to use topical therapy as an adjunct in the case of residual carcinoma in situ at a margin, and to perform careful follow-up.

Mohs Micrographic Surgery

Mohs microsurgery has historically had a positive impact on the management of penile carcinoma in situ and small superficially invasive tumors. As originally described by Mohs and colleagues (1985), it involves layer-by-layer complete excision of the penile lesion in multiple sessions (fixed tissue technique), with microscopic examination of the undersurface of each layer. Its sequential microscopic guidance offers improved precision and control of the negative margin while maximizing organ preservation. In a series of 29 consecutive cases of penile squamous cell carcinoma, the primary tumor was eradicated in 23 (92%) of 25 patients available for follow-up. Local recurrences were highly associated with tumor size (3 cm), advanced stage, and failure of previous definitive therapy (Mohs et al, 1992). These excellent results using a fixed tissue technique have not been reproduced with the currently used frozen-section methodology. Shindel and associates (2007) treated 33 patients with stage Tis (26 patients), T1 (4 patients), T2 (7 patients), and T3 (4 patients) penile cancer. Five procedures were terminated with positive margins. Of 25 patients with mean follow-up of 58 months, 8 (32%) developed recurrence. However, 7 of 8 were re-treated successfully with Mohs surgery. One patient who had progression of his disease died from it. Thus Mohs microsurgery, as currently performed, may offer no additional benefit over surgical excision with intraoperative frozen-section assessment of margin status.

Laser Ablation

The four most widely used laser energy sources are the CO₂, argon, Nd:YAG, and KTP lasers (Carpiniello et al, 1987; Malloy et al, 1988; von Eschenbach et al, 1991). Although the CO₂ laser has been widely used previously, the superficial depth of penetration (limited to 0.1 mm) makes it less than optimal for the treatment of penile carcinoma in situ or small T1 tumors. When the CO₂ laser is used, local recurrence rates have been shown to be as high as 50% (Bandieramonte et al, 1988; van Bezooijen et al, 2001). Conversely, the Nd:YAG laser results in protein denaturation at a depth of up to 6 mm by emitting at a wavelength of 1060 nm. Overall recurrence rates after laser ablation have been reported to be 7.7% for penile carcinoma in situ and have ranged from 10% to 25% for T1 lesions (Malloy et al, 1988; Windahl and Hellsten, 1995; Tietjen and Malek, 1998), but results from more contemporary series using the Nd:YAG laser exclusively have been more encouraging. Frimberger

and colleagues (2002a) treated 29 men with carcinoma in situ and stage T1 tumors, combining Nd:YAG laser ablation with tumor base biopsies to ensure negative surgical margins. Only two recurrences (6.9%) were reported at a mean follow-up of 46.7 months, which is comparable to recurrence rates after partial penectomy. In an effort to reduce the incidence of positive surgical margins, Frimberger and associates (2002b) have proposed the use of autofluorescence and 5-aminolevulinic acid–induced fluorescence for targeting of frozen-section biopsy specimens.

Laser ablation is feasible and may achieve results equivalent to those of extirpative surgery, especially when it is performed in well-selected patients in conjunction with frozen-section biopsies. In addition, laser ablation has been associated with high rates of resumption of sexual activity (75%) and overall satisfaction (78%) (Windahl et al, 2004). However, until additional long-term studies become available, laser ablation should be performed with the understanding that local recurrences may develop and that close surveillance and patient self-examination are necessary for early detection. Although well-selected patients who develop small recurrent lesions may be candidates for repeated laser ablation, recurrences are best treated with wide local excision or partial amputation.

Contemporary Penile Amputation

Penile amputation remains the standard therapy for patients with deeply invasive or high-grade cancers. **Partial or total penectomy should be considered in patients exhibiting adverse features for cure by organ preservation strategies.** These are consistently associated with tumors of size 4 cm or more, grade 3 lesions, and those invading deeply into the glans urethra or corpora cavernosa (Mohs et al, 1992; Gotsadze et al, 2000; Kiltie et al, 2000). Because recurrence rates are higher with organ-preserving strategies, compliance with follow-up is also a consideration in recommending organ preservation versus amputation. Fortunately, most patients with recurrences that are detected and treated early are not adversely affected with respect to survival (Lont et al, 2006).

On the basis of contemporary results, organ preservation strategies should be discussed with patients exhibiting optimal tumor characteristics (stages Tis, Ta, T1; grade 1 and grade 2 tumors) to assist them in making informed decisions about therapy. (See Table 37-2 for treatment modalities for the primary penile tumor.)

KEY POINTS: SURGICAL TREATMENT OF THE PRIMARY TUMOR

- Patients with small lesions of low grade and stage (Tis, Ta, T1; grade 1 and grade 2) are the optimal candidates for organ preservation to maintain sexual quality of life.
- The goals of organ preservation are to maintain glanular tissue for sensory purposes when possible and/or to maintain penile length when glans penis preservation is not possible.
- Surgical modalities include limited excision strategies, Mohs surgery, and laser ablation.
- Local recurrence rates overall after organ preservation are higher than with traditional amputation; however, when local recurrences are detected and treated, early survival does not appear to be adversely affected.
- Amputation remains the standard for large or deeply invasive lesions, to gain rapid tumor control.

TREATMENT OF THE INGUINAL NODES

The presence and the extent of metastasis to the inguinal region are the most important prognostic factors for survival in patients with squamous penile cancer. These findings affect the prognosis

TABLE 37-2 Treatment of the Primary Penile Tumor

STAGE	TREATMENT
Tis (glans)	Laser therapy, glans resurfacing; alternative: topical therapy
Ta, Tis (foreskin, shaft skin)	Surgical excision to achieve negative margin; alternatives: laser therapy, topical therapy (Tis only)
Ta, T1 grade 1-3 (glans)	Therapy based on size and position of lesion as well as potential side effects, excision, glans resurfacing procedures, glansectomy, radiotherapy (not indicated for Ta)
Ta, T1 grade 1-3 (foreskin, shaft)	Complete surgical excision to achieve negative margin
T2 (glans) without gross cavernosum involvement	Total glansectomy with or without corpora cavernosa transection to achieve negative surgical margins, partial penectomy, radiotherapy
T2 (corporeal invasion), T3	Partial or total penectomy
T4 (adjacent structures)	Consider neoadjuvant chemotherapy with surgical consolidation for responding patients if baseline resectability is a concern
Local disease recurrence after conservative therapy	Complete surgical excision to achieve negative surgical margins; may require partial or total penectomy; select patients with superficial low-grade recurrences may be candidates for repeat penile-conserving procedure
Radiotherapy	Select patients with T1-T2 tumors involving glans, coronal sulcus <4 cm

of the disease more than do tumor grade, gross appearance, and morphologic or microscopic patterns of the primary tumor.

Unlike with many other genitourinary tumors, which mandate systemic therapeutic strategies once metastasis has occurred, lymphadenectomy alone can be curative and should be performed. The biology of squamous penile cancer is such that it exhibits a prolonged locoregional phase before distant dissemination, providing a rationale for the therapeutic value of lymphadenectomy.

However, owing to the morbidity of traditional lymphadenectomy especially among patients with clinically negative groins, contemporary controversial issues include (1) the selection of patients for lymphadenectomy versus careful observation; (2) the types of procedures to correctly stage the inguinal region with low morbidity; and (3) multimodal strategies to improve survival among patients with bulky inguinal metastases.

In this rare disease, prospective randomized trials have not been performed to answer many of these questions. However, with the use of retrospective and prospective clinicopathologic data from several centers, treatment strategies are presented using the available data.

metastases on the basis of histologic examination of the inguinal nodes or repeated normal examination findings over time; the average 5-year survival rate was 73% (46% to 100%). In patients with resected inguinal metastases the 5-year survival averaged 60% (0% to 86%), but this varied widely and was directly attributable to the extent of nodal metastasis (see Table 37-3). This point is illustrated in several series shown in Tables 37-3 and 37-4. Patients with minimal nodal metastases (usually two or less) exhibited 5-year survivals that ranged from 72% to 88% compared with 0% to 50% when a greater degree of nodal involvement was present (see Table 37-4).

The extent of cancer in a lymph node was also of prognostic significance. Ravi (1993a) noted ENE of cancer in lymph nodes 4 cm in size, and only 1 of 17 patients (6%) undergoing lymphadenectomy survived 5 years. Finally, pelvic lymph node involvement has been a particularly ominous finding with respect to long-term survival; the combined results of several small series reveal an average 5-year survival of 14% when pelvic nodal

metastases are present (Table 37-5). Taken together, these data suggest that the pathologic criteria associated with long-term survival after attempted curative surgical resection of inguinal metastases (i.e., 80% 5-year survival) include minimal nodal disease (up to two involved nodes in most series), unilateral involvement, no evidence of ENE of cancer, and absence of pelvic nodal metastases.

Presence of Palpable Adenopathy as a Selection Factor for Inguinal Dissection

One can conclude from these data that it is advantageous to find and to treat nodal metastasis at the earliest possible opportunity. Data in Table 37-3 suggest that the presence of palpable adenopathy is associated with proven nodal metastasis in about 43% of cases on average (range 8% to 64%). In the remainder, lymph node enlargement is secondary to inflammation. Persistent adenopathy

after treatment of the primary lesion and 4 to 6 weeks of antibiotic therapy is most often the consequence of metastatic disease. Similarly, the development of new adenopathy during follow-up is much more likely to be caused by tumor than inflammatory response. Thus historically a course of antibiotics was recommended for patients with suspicious nodes to potentially discern metastasis from cancer (Srinivas et al, 1987). However, several authors have raised the issue that this causes a significant delay and could affect survival, especially among patients who are likely to be truly positive by virtue of the stage or grade of the primary tumor (Kroon et al, 2005b; Pettaway et al, 2007). An alternative approach for such patients is to perform fine-needle aspiration cytology of palpable nodes either at the time of or immediately after treatment of the primary tumor. In the case of a positive result, definite therapy can be planned without a 4- to 6-week delay. Saisorn and associates (2006) reported a 93% sensitivity and a 91% specificity in 16 patients with palpable adenopathy (mean size 1.47 cm) undergoing fine-needle aspiration before lymphadenectomy. The recommendation for this procedure among patients with palpable nodes

was also incorporated in the European Association of Urology (EAU) Penile Cancer Guidelines. Thus, although treatment of the primary tumor and a period of antibiotics are useful to help sterilize the inguinal region, this practice is no longer advocated as a tool to select patients who either should or should not undergo lymphadenectomy. Should the fine-needle aspiration result be negative, depending on clinical suspicion, close observation, repeat aspiration, or excisional biopsy is performed because the false-negative rate of fine-needle aspiration cytology was 20% to 30% in two other older series (Scappini et al, 1986; Horenblas et al, 1991).

Evolving Indications for Lymphadenectomy in Patients without Palpable Adenopathy

Immediate versus Delayed Surgery

Considering the value of early detection and treatment of metastasis, should inguinal lymphadenectomy (ILND) be routinely performed in patients with clinically normal groin examination findings at the time of presentation of the primary lesion? This was the most controversial issue in the management of patients with squamous penile cancer previously; however, the pendulum has moved toward earlier lymphadenectomy in selected patients with penile cancer. As noted, the cure rate with ILND when nodes are positive for malignancy may be as high as 80%. A cure rate of this magnitude with surgery in the face of regional nodal metastases parallels the urologist's experience with testicular cancer, in which retroperitoneal lymphadenectomy provides cure in many patients with minimal nodal metastasis. In contrast, for other common genitourinary malignant neoplasms—bladder, prostate, and kidney—surgical cure in the presence of regional nodal metastases is rare. Given that node dissection can cure metastatic penile cancer, why is there debate about whether the procedure should be performed, especially given that regional node dissections are often advocated in other malignant neoplasms when evidence of their efficacy is marginal at best?

Morbidity versus Benefit

The reluctance to advocate automatic ilioinguinal lymphadenectomy (IILND) in all patients with penile cancer stems from the substantial morbidity the procedure can produce, as opposed to the relatively limited postoperative morbidity of pelvic or retroperitoneal lymphadenectomies. Early complications of phlebitis, pulmonary embolism, wound infection, flap necrosis, and permanent and disabling lymphedema of the scrotum and lower limbs were frequent after both inguinal and ilioinguinal node dissections (Skinner et al, 1972; Johnson and Lo, 1984a; McDougal et al, 1986; Fraley et al, 1989). Postoperative complications have been reduced by improved preoperative and postoperative care; advances in surgical technique; plastic surgical consultation for myocutaneous flap coverage; and preservation of the dermis, Scarpa fascia, and saphenous vein, as well as modification of the extent of the dissection (Catalona, 1988; Colberg et al, 1997; Bevan-Thomas et al, 2002; Coblenz and Theodorescu, 2002; Nelson et al, 2004). In the University of Texas MD Anderson Cancer Center experience, both the incidence and severity of lymphedema and skin edge necrosis were significantly decreased (Table 37-6, Fig. 37-3) (Bevan-Thomas et al, 2002).

Furthermore, experience has suggested that lymphadenectomy in the setting of microscopic disease may be less likely to produce complications than node dissection in the presence of bulky nodal metastases (Fraley et al, 1989; Ornellas et al, 1994; Coblenz and Theodorescu, 2002). This is presumably because of the reduced amount of lymphatic tissue removed, preservation of venous drainage, and less blood supply compromised. Together these factors affect the viability of skin flaps and lymphatic flow.

Mortality after ILND has been reported in association with surgery performed concomitantly with penectomy and after

Figure 37-3. Postoperative appearance after contemporary lymphadenectomy. The patient's status is post right ilioinguinal lymphadenectomy and left superficial inguinal dissection for stage T2N1M0 squamous penile cancer. Mild edema is visible on the left 10 months after surgery. Patient remains without disease at 9 years.

Clearly, lymphadenectomy is not a trivial concern, even though morbidity appears to be decreasing. If a policy of routine lymphadenectomy were adopted in all patients with clinically negative lymph nodes, the average risk of false-negative examination findings (metastasis is actually present) would be approximately 29%, with wide-ranging variation (see Table 37-3). Stated another way, an average of 70% of patients could be subjected to the morbidity of ILND with no benefit. Potential reasons for false-negative examination findings include obesity, preexisting edema, and changes from prior therapy (radiation, inguinal surgery).

One alternative to immediate lymphadenectomy for all patients has been to observe patients with normal findings on inguinal examination. Lymphadenectomy is subsequently reserved for those patients who develop palpable lymph nodes. The relevant question then becomes, can a delayed therapeutic dissection effectively salvage patients who have inguinal recurrence?

Several studies have analyzed the survival of men undergoing early versus delayed lymphadenectomy according to pathologic evaluation of nodal status. McDougal and coworkers (1986) reported a series of 23 patients with invasive primary lesions and nonpalpable nodes; 9 patients were treated with immediate adjunctive lymph node dissection (6 had positive findings), and 14 were treated with surveillance and delayed lymph node dissection. The 5-year survival in the node-positive immediate adjunctive lymphadenectomy group was 83% (5 of 6 patients), whereas in the surveillance group the 5-year survival was 36% (5 of 14 patients). However, only 1 patient in the surveillance group had a node dissection. Presumably, the other 9 patients had progressed to inoperable local tumor or distant disease before presentation, emphasizing the role of careful, frequent follow-up and the difficulty of enforcing it. A third subset in this series had palpable nodes at presentation and had immediate therapeutic lymph node dissection, with 10 of 15 patients (66%) surviving 5 years (McDougal et al, 1986). The best results were from immediate adjunctive lymph node dissection (83%), with the next best from immediate therapeutic lymphadenectomy (66%). The worst results were from the surveillance and delayed lymphadenectomy group (36%), in whom dissection was delayed until palpable nodes developed. The interval of opportunity for cure in this third group appears to have been lost.

Similarly, Fraley and associates (1989) reported that immediate adjunctive lymphadenectomy resulted in a 5-year disease-free survival in 6 of 8 node-positive patients (75%) compared with 1 of 12 patients (8%) who had been observed and then treated with delayed lymphadenectomy when nodal enlargement occurred. Six other patients in that series also had unresectable adenopathy after initial surveillance, and all died of their disease. Although only 2 of 6 patients who had immediate lymphadenectomy had more than two

palliative inguinal dissection. In both scenarios it was related to sepsis (Bevan-Thomas et al, 2002). An operative mortality of 3.3% was reported in earlier series (Beggs and Spratt, 1964). However, Johnson and Lo (1984a) and others (Ravi, 1993b; Ornellas et al, 1994; Coblenz and Theodorescu, 2002; Nelson et al, 2004) have reported no mortality in more recent series. Appropriate selection of patients along with routine preoperative antibiotic therapy and wound care to avoid septic complications has minimized this event.

positive nodes, all the patients treated by delayed lymph node dissection had three or more positive nodes.

Three other series suggest that early lymphadenectomy for varying degrees of “suspicious” or clinically positive nodes improves survival compared with the “surveillance” or delayed intervention approach in patients with clinically negative nodes (Johnson and Lo, 1984b; Ornellas et al, 1994; Kroon et al, 2005b). A series from the University of Texas MD Anderson Cancer Center compared 5-year disease-free survival of 14 patients undergoing early lymphadenectomy for clinically suspicious and histologically node-positive disease with that of 8 patients who were observed and later underwent lymphadenectomy when clinical nodal enlargement was undisputed (Johnson and Lo, 1984b). The primary tumors were of similar stage. The 5-year disease-free survival was 57% for early lymphadenectomy compared with 13% for delayed node dissection. Of note, the number of involved nodes in the immediate lymphadenectomy group (median, two) was half that of the delayed lymphadenectomy group (median, four), and no patient with more than two positive nodes survived more than 5 years.

Kroon and associates (2005b) from the Netherlands Cancer Institute compared survival of 20 patients found to have positive lymph nodes subsequent to prophylactic DSNB with that of 20 patients who underwent delayed inguinal dissection after proven nodal metastasis. The 3-year survival for patients detected during close surveillance was only 35% compared with 84% ($P = .0017$) for those undergoing early dissection. Pathologic evaluation of involved lymph nodes revealed ENE of cancer among 19 of 20 patients in the delayed group versus only 4 of 20 patients ($P = .001$) in the early group. Thus, despite careful follow-up, survival was adversely affected by the extent of cancer in involved lymph nodes.

A single large study from India disputes the magnitude of the value of early prophylactic dissection. Ravi (1993b) performed early prophylactic dissection in 113 patients with invasive penile cancer and compared the 5-year survival with that of 258 similarly staged patients who were initially observed. In the “early” group, 20 patients (18%) were found to have metastases, and all patients survived 5 years. The recurrence rate in the observed group was only 8% (21 patients). However, the 5-year survival in the patients who experienced recurrence was only 76% (compared with 100% in the early lymphadenectomy group). The enhanced survival of patients undergoing surveillance in India compared with other countries is probably attributable to patient selection factors, strict adherence to follow-up schedules, and aggressive treatment approach for recurrent disease (a combination of radiation and surgical resection) (Ravi, 1993a).

Thus, six series reveal an improvement in survival for patients undergoing early therapeutic versus delayed therapeutic dissection. Furthermore, five of the six series show that delayed therapeutic dissection can rarely salvage patients who experience recurrence. Taken together, these data suggest that a policy of immediate adjunctive or early lymphadenectomy gives greater assurance that surgical intervention will occur when tumor volume is small (see Table 37-4) (Johnson and Lo, 1984a; Fossa et al, 1987; Srinivas et al, 1987; Fraley et al, 1989; Ravi, 1993b; Kroon et al, 2005b).

Impact of Primary Tumor Histologic Features on Predicting Occult Nodal Metastasis

Although early lymphadenectomy improves survival in patients with inguinal metastases, the challenge remains to identify those patients who are truly lymph node negative to avoid the morbidity of traditional lymphadenectomy. Data gained from analysis of a variety of histopathologic variables within the primary penile tumor allow the classification of patients into higher and lower risk groups for lymph node metastasis (McDougal, 1995; Lopes et al, 1996; Theodorescu et al, 1996; Solsona et al, 2001; Ficarra et al, 2006).

Patients with primary tumors exhibiting carcinoma in situ or verrucous carcinoma have little or no risk for metastasis. Only two cases of metastasis in association with carcinoma in situ have been

reported, and none of 47 cases of penile verrucous carcinoma has been shown to metastasize (Avrach and Christensen, 1976; Johnson et al, 1985; Seixas et al, 1994; Eng et al, 1995). Thus, patients with both Tis and Ta penile cancer are included in the low-risk group for inguinal metastases (Solsona et al, 2001, 2004).

In contrast, patients with corporeal invasion (stage pT2) in the penile tumor exhibit a high risk for metastasis. The average risk for inguinal metastasis among 225 patients in seven different series was 59% (Table 37-7). The risk for metastasis among patients exhibiting corporeal invasion was similar irrespective of whether palpable adenopathy was present.

Stage T1 penile cancers exhibit involvement of the subepithelial connective tissue only and lack involvement of the corpus spongiosum, corpora cavernosa, or urethra (Edge et al, 2010). Similarly staged tumors historically have been associated with a 4% to 14% incidence of nodal metastasis (Solsona et al, 1992; Villavicencio et al, 1997; Hall et al, 1998). Theodorescu and colleagues (1996) noted one exception to this relatively low rate of metastatic disease; 58% of patients (14 of 24) with pT1 primary tumors and initially negative nodes on clinical assessment subsequently developed inguinal nodal metastases. These data suggest that other variables present within the penile cancers of the cohort of patients studied (i.e., tumor grade and presence of vascular invasion) may have modified the effect of tumor stage on metastasis.

Several authors have evaluated the risk of nodal metastasis for stage T1 lesions according to tumor grade (Table 37-8). Among 73 patients with T1 grade 1 or grade 2 primary tumors, metastasis occurred in only 5 patients (7%). Recent data from Naumann and coworkers (2008), however, suggested that among T1 grade 2 tumors specifically, the risk of metastases could be higher than previously described. Among four series reporting specifically on the T1 grade 2 subset, in 129 initially node-negative patients, metastases occurred in 18 (14%) (see Table 37-8). However, 5 patients in this subset also exhibited either lymphatic or venous invasion (an adverse prognostic feature, see later). Ficarra and colleagues (2006) developed the first penile cancer nomogram using data from 175 patients. Based on tumor thickness and growth pattern, patients with T1 grade 2 tumors exhibited metastatic rates of 5% to 20%. Thus grade 2 tumors represent a heterogeneous group in which the histologic criteria used to describe grade 2 and the presence or absence of other poor prognostic features ultimately determine prognosis (Cubilla, 2009). In this regard the EAU guidelines assigned patients with T1 grade 2 tumors to the intermediate-risk category in which the risk of lymph node metastasis is greater than 16% (low risk) and less than 68% (high risk) (Solsona et al, 2004; Pizzocaro et al, 2010).

The presence of vascular invasion as a prognostic indicator of inguinal lymph node metastasis in squamous penile cancer is

now evident (Fraley et al, 1989; Lopes et al, 1996; Heyns et al, 1997; Slaton et al, 2001; Ficarra et al, 2005). Lopes and colleagues (1996) studied the prognostic value of lymphatic invasion in 146 patients with penile cancer. In a univariate analysis, clinical nodal stage, tumor thickness, lymphatic and venous embolization, and urethral infiltration were all associated with lymph node metastasis. However, subsequent to multivariate analysis, only venous and lym-

phatic invasion remained significant predictors for positive lymph nodes. Data from the University of Texas MD Anderson Cancer Center revealed that vascular invasion was absent in all patients with T1 tumors (Slaton et al, 2001). These patients were also lymph node negative at surgery. In contrast, patients with stage pT2 primary tumors exhibited nodal metastasis in 75% of cases (15 of 20) when vascular invasion was present but in only 25% of cases (3 of 12) when it was absent.

Ficarra and colleagues (2005) described prognostic factors for lymph node metastasis in 175 patients undergoing surgery for penile cancer in a multicenter study from the Northeast Uro-Oncological Group from Italy. Subsequent to multivariate statistical analysis, the presence of venous or lymphatic invasion and pathologic invasion of the corpus spongiosum or urethra were the only independent risk factors for lymph node metastasis among patients who were clinically lymph node negative. Taking this a step further and including the variables of tumor thickness, growth pattern, grade, venous or lymphatic invasion, corpus spongiosum or cavernosum involvement, urethral involvement, and palpable lymph nodes, Ficarra and colleagues (2006) developed a nomogram predicting inguinal lymph node involvement. The most important variables were venous or lymphatic invasion and the presence of palpable nodes in multivariate analysis. The concordance index of the nomogram was very good at 0.876. However, because of the complexity of the nomogram variables included, external validation of the nomogram has to date not been accomplished.

The presence of perineural invasion (Velazquez et al, 2008) and the microscopic front pattern of invasion (Guimares et al, 2006) have also been shown in recent studies to provide independent information with which to stratify a patient's risk of lymph node metastasis.

Molecular Prognostic Markers

Analysis of gene expression in penile cancer may have future implications with respect to the prediction of lymph node metastasis or survival. A review by Muneer and colleagues (2009) describes the status of several genes evaluated in tissue or serum that could have future prognostic implications with respect to predicting lymph node status or survival (Table 37-9). Zhu et al (2010) incorporated p53 expression into a nomogram that included T stage, grade, and the presence or absence of lymphovascular invasion. When compared with the EAU risk classification, the nomogram incorporating p53 would have resulted in 13 fewer lymph node dissections per

100 patients, thus decreasing morbidity. These data suggest the potential value of incorporating molecular features into models to enhance prognostication. Presently, however, standardization of methodologies for assessment of gene expression and the lack of large tissue banks with well-annotated clinical data for validation studies hamper efforts to rigorously evaluate the potential usefulness of such biomarkers. Prospective multi-institutional studies analyzing both pathologic and molecular features are needed to further validate which pathologic and molecular variables best stratify a patient's risk for metastasis and survival.

Contemporary Evolving Indications for Expectant Management of the Inguinal Region

Data reviewed in the preceding paragraphs along with consensus guidelines demonstrate that patients with primary tumors exhibiting carcinoma in situ (Tis), verrucous carcinoma (Ta), and stage T1, grade 1 tumors exhibit a relatively low incidence of positive lymph nodes overall (0% to 16%) and are optimal candidates for watchful waiting strategies (Pompeo et al, 2009; Pizzocaro et al, 2010). Recommendations for the management of T1 grade 2 tumors vary based on quoted rates of subsequent metastases. The former EAU guideline (Solsona et al, 2004), although classifying such cases in the intermediate-risk group, recommended observation for T1 grade 2 tumors that lacked vascular invasion and exhibited a superficial growth pattern (i.e., absence of any other adverse features). This guideline was recently modified to recommend an inguinal staging procedure for this group of patients (Pizzocaro et al, 2010). Given the low rate of metastases of 9% overall in a recent study, we agree with the Société Internationale d'Urologie/International Consultation on Urological Diseases (ICUD) recommendation that these patients may also be considered for observation (Pompeo et al, 2009; Hughes et al, 2010; see Table 37-9). This grouping of T1 grade 2 patients corresponds to the current AJCC TNM T1a classification (Edge et al, 2010). All other cases should be considered for surgical staging.

Patients with AJCC stage T1b or greater (see Table 37-1) as a group exhibit at least a 50% incidence of inguinal metastasis, so an inguinal staging procedure appears warranted. In addition, non-compliant patients with invasive primary tumors should be offered an inguinal staging procedure versus observation. Table 37-10 provides a guideline for more intensive follow-up of high-risk patients, especially within the first 2 years. It is imperative for both the patient and the physician to adhere to such follow-up agreements and to be willing to intervene immediately if initial inguinal parameters change. Leijte and colleagues (2008) have documented that only a third of patients who were initially node negative but who subsequently develop an inguinal recurrence survive 5 years.

Indications for Modified and Traditional Inguinal Procedures

Modified Procedures

In patients with no evidence of palpable adenopathy who are selected to undergo inguinal procedures by virtue of adverse prognostic factors within the primary tumor, the goal is to define whether metastases exist with minimal morbidity for the patient. A variety of treatment options for this purpose have been reported and include fine-needle aspiration cytology, node biopsy, sentinel lymph node biopsy, extended sentinel lymph node dissection, dynamic sentinel lymph node biopsy, superficial dissection, and modified complete dissection. The technical aspects of many of these procedures are beyond the scope of this chapter but may be found in Chapter 39 and in the references by Horenblas and colleagues (2000) and Spiess and coworkers (2009).

Fine-Needle Aspiration Cytology. The experience with aspiration of clinically negative inguinal nodes guided by either lymphangiography or ultrasonography is limited. Scappini and associates (1986) performed fine-needle aspiration cytology under pedal or penile lymphangiography for nodal localization in 29 patients. Of 20 patients who had lymphadenectomy for histologic confirmation, there was complete agreement between aspiration cytology and histologic results. However, 2 of 9 patients whose cytologic analysis was negative subsequently died of metastatic disease, a presumptive 20% false-negative result. A series from Horenblas and colleagues (1991) also found that the sensitivity of fine-needle aspiration cytology was approximately 71% in 18 patients with clinically negative lymph nodes. This finding and the technical difficulty with lymphangiography make aspiration less practical as a staging technique for patients with no palpable lymph nodes. Kroon et al (2005a) described fine-needle aspiration cytology guided by ultrasonography as a preliminary study to surgical staging with DSNB. Thirty-four groins in 27 patients with clinically negative groins were found to have suspicious nodes by ultrasound examination and were aspirated. However, the sensitivity of the technique was only 39% subsequent to surgical staging. Thus, at present, fine-needle aspiration cytology of clinically negative groins does not exhibit the sensitivity for it to be relied on as a staging modality. However, direct aspiration of palpable inguinal nodes is easily performed, exhibited a sensitivity of 93% in a recent study, and, if positive, provides immediate information with which to advise patients about further treatment (Saisorn et al, 2006).

Sentinel Lymph Node Biopsy, Extended Sentinel Lymph Node Dissection, and Node Biopsy. The concept of sentinel lymph node biopsy as described by Cabanas (1977) is predicated on detailed penile lymphangiographic studies that have demonstrated consistent drainage of the penile lymphatics into a sentinel node or group of nodes located superomedial to the junction of the saphenous and femoral veins in the area of the superficial epigastric vein. In this series, when this sentinel node was negative for tumor, metastases to other ilioinguinal lymph nodes did not occur. Metastases to this node indicated the need for a complete superficial and deep inguinal dissection.

The accuracy of the sentinel node histology to identify inguinal node metastases was, however, questioned by a number of reports (Perinetti et al, 1980; Fowler, 1984; Wespes et al, 1986). Because nodal metastases became palpable within 1 year of sentinel node biopsy with normal findings in some patients in these series, a false-negative biopsy result must be presumed. In one large series, 5 of 41 patients (12%) with normal findings on sentinel node biopsy subsequently developed inguinal node metastases (Fossa et al, 1987). In Cabanas's series (1992), 3 of 31 patients with negative sentinel nodes died of disease, suggesting a false-negative rate for identifying metastases of 10%. McDougal and associates (1986) reported a 50% false-negative rate with inguinal node biopsy. A report by Pettaway and colleagues (1995), in which additional nodes around the sentinel node area were also removed, revealed that even this extended dissection was associated with a

false-negative rate of 25%. The authors hypothesized that false-negative inguinal node biopsies were the result of anatomic variation in the position of the sentinel node within the inguinal field. **Thus, biopsies directed to a specific anatomic area can be unreliable in identifying microscopic metastasis and are no longer recommended.**

Dynamic Sentinel Node Biopsy. DSNB offers the potential for precise localization of the sentinel node with the lowest morbidity of any surgical staging technique (Kroon et al, 2005c). The goal of DSNB is to define where in the inguinal lymph node field the sentinel lymph node resides through use of a combination of visual (vital blue dyes) or gamma emission (hand-held gamma probe) techniques at the time of surgery.

The technique has been studied in patients with malignant melanoma and breast and vulvar carcinomas who required evaluation of the regional lymph nodes (Morton et al, 1992; Levenback et al, 1994; Albertini et al, 1996; Gershenwald et al, 1999). The technique involves intradermal injection of a vital blue dye (isosulfan blue or patent blue dyes) or technetium-labeled colloid adjacent to the lesion. The dye (or radioactive tracer) is transported by the afferent lymphatics to a specific node in the regional nodal basin. This node is designated the sentinel lymph node. In Morton's series of 237 patients with melanoma, the sentinel lymph node was identified in 194 patients. These patients then underwent full regional lymphadenectomy, with a false-negative sentinel node in only 1% of cases.

Several studies evaluating the results of DSNB as a staging tool in penile cancer are now available. Kroon and associates (2004) updated the Netherlands Cancer Institute experience, describing their experience using the combination of preoperative lymphoscintigraphy and intraoperative intradermally injected blue dye in 123 patients with penile cancer. They identified a sentinel node in 98% of patients, for a sensitivity rate of 82% and a false-negative rate of 18% (6 patients). Four of the 6 patients subsequently died of disease progression. Spiess and associates (2007) also noted a false-negative rate of 25% among 31 patients undergoing DSNB. The Netherlands Cancer Institute group subsequently instituted several changes, including (1) routine serial sectioning of the involved lymph nodes along with cytokeratin immunohistochemistry, (2) routine exploration of groins with low or no signal subsequent to preoperative or intraoperative studies, and (3) inguinal ultrasonography with fine-needle aspiration to detect subtle architectural changes (nonpalpable) in positive lymph nodes that could result in the redistribution of lymphatic flow (Kroon et al, 2005a).

In a multicenter update that included patients assessed with the modified DSNB protocol from two high-volume centers (the Netherlands Cancer Institute and St. George's Hospital in London) the false-negative rate was 7% (6 patients) among 323 patients (Leijte et al, 2009b). Three of 6 patients with recurrence (50%) either died or developed distant metastases. **Thus DSNB, when performed at high-volume centers using a standardized protocol, has an acceptable sensitivity, but deaths from penile cancer among initially node-negative patients still occurred.** This limits the applicability of this strategy to larger centers with experienced surgeons and nuclear medicine specialists.

Superficial and Modified Complete Inguinal Dissection. Both superficial inguinal and modified complete dissections have been proposed as staging tools for the patient without palpable inguinal lymphadenopathy. Superficial node dissection involves removal of those nodes superficial to the fascia lata. A complete IILND (removal of those nodes deep to the fascia lata contained within the femoral triangle as well as the pelvic nodes) is then performed if the superficial nodes are positive at surgery by frozen-section analysis. The rationale for superficial dissection is that two series have shown no positive nodes deep to the fascia lata unless superficial nodes were also positive (Pompeo et al, 1995; Puras-Baez et al, 1995). Furthermore, Spiess and colleagues (2007) showed that among the lymph node-negative cohort of patients undergoing DSNB followed by completion superficial dissection, no patient with a negative superficial dissection experienced recurrence, with more than 3 years of follow-up. A complete modified inguinal dissection was originally

proposed by Catalona (1988) and involves smaller skin incision, limited field of inguinal dissection, preservation of the saphenous vein, and thicker skin flaps. This technique also avoids having to transpose the sartorius muscle to cover exposed femoral vessels. Unlike in superficial dissection, deep nodes within the fossa ovalis are also removed. Two reports involving 21 patients have confirmed the value of this technique, when it is properly performed, for identifying microscopic metastases with minimal morbidity (Parra, 1996; Colberg et al, 1997).

Thus, either superficial or complete modified inguinal dissection should adequately identify microscopic metastases in patients with clinically normal inguinal examination findings, without the need for a pelvic dissection if the inguinal nodes are negative. The disadvantage of the modified dissections is the higher overall complication rate (12% to 35%) when compared with DSNB (5% to 7%) (Kroon et al, 2005c; Spiess et al, 2009).

Limited dissections have the following advantages: More information is provided than by biopsy of a single node or group of nodes; the possibility of not identifying the sentinel node is limited by removal of all potential first-echelon nodes; and the dissection is readily performed by any surgeon experienced in inguinal surgery without the need for specialized equipment.

Minimally Invasive Inguinal Lymphadenectomy Using Laparoscopy or Robotic Techniques. Both the laparoscopic and robotic approaches to the inguinal region offer the potential for removing all of the inguinal lymph nodes at risk for disease while minimizing complications. The technical details of the contemporary procedure and early results have been described (Sotelo et al, 2007; Tobias-Machado et al, 2007; Matin et al, 2013). To date, the results of laparoscopic and robotic ILND have been comparable to those of open inguinal lymph dissection with comparable node counts achieved in both. A single case of inguinal recurrence reported at 12 to 33 months of follow-up and minor complications in about 20% of patients have been reported (Sotelo et al, 2009). However, in one study using a laparoscopic approach with over 600 days of follow-up, Master and colleagues (2012) noted minor complications in 27% of patients, with major complications noted in 14.6%. These were mainly infectious in nature and were managed with intravenous antibiotics or incision and drainage. Of note, among 41 dissections there was only a single case of skin edge necrosis. Matin and colleagues (2013), using a robotic-assisted approach, noted in a phase 1 pilot study that inguinal dissection appeared equivalent to an open approach in 18 of 19 (94.7%) patients when verified by a second surgeon using an open incision to inspect the same groin. Minimally invasive approaches, although promising as an inguinal staging tool, will require further validation with larger patient numbers and longer follow-up to better determine efficacy and complication rates compared with traditional approaches or DSNB.

Traditional Inguinal and Ilioinguinal Lymphadenectomy

In patients with resectable metastatic adenopathy, the potential therapeutic value of lymphadenectomy justifies the morbidity of treatment. The goals are to eradicate all obvious cancer, to provide coverage for exposed vasculature, and to provide rapid wound healing (primary closure or myocutaneous flap coverage). Several issues remain with respect to surgical decision making.

Should ILND be bilateral rather than unilateral for patients with unilateral adenopathy at initial presentation of the primary tumor? The answer to this question is yes. The anatomic crossover of penile lymphatics is well established, and bilateral drainage is the rule. In 43 of 54 patients (79%) undergoing intraoperative lymph node mapping at the Netherlands Cancer Institute, lymphatic drainage from the penis was bilateral (Horenblas et al, 2000). The contralateral node dissection may be limited to the area superficial to the fascia lata if no histologic evidence of positive superficial nodes is found at surgery by frozen-section analysis. Clinical support for a bilateral procedure is based on the finding of contralateral metastases in more than 50% of patients so treated,

even if the contralateral nodal region was normal on palpation (Ekstrom and Edsmyr, 1958).

Should bilateral ILND be performed in patients with unilateral lymphadenopathy some time after the initial presentation and treatment of the primary tumor? It is generally believed that bilateral node dissection in this setting is not necessary. The recommendation of unilateral rather than bilateral node dissection with delayed presentation of unilateral lymphadenopathy is supported by the elapsed disease-free interval of observation on the normal side. If one assumes that nodal metastases will enlarge at the same rate, the clinical palpation of nodal metastases, if present in both groins, should appear at approximately the same time. The absence of clinical adenopathy on one side despite prolonged observation suggests freedom from disease on that side (Ekstrom and Edsmyr, 1958). However, this concept may not apply to all patients with delayed recurrence. Horenblas and colleagues (2000) noted that in patients with two or more unilateral metastases, contralateral occult metastases were noted in 30% of cases. Thus, in patients with a bulky unilateral recurrence, a contralateral inguinal staging procedure should be considered. Considering the current treatment recommendations for bilateral inguinal staging procedures in men at high risk for metastasis and the definition of low-risk groups for metastasis by use of available prognostic markers, this scenario should rarely occur.

Should pelvic lymphadenectomy (PLND) be performed in all patients with inguinal metastases, considering its potential for added morbidity and relatively low therapeutic value? This issue remains controversial, but recent data suggest that PLND may be omitted in select patients with limited inguinal metastases (Lont et al, 2007; Zhu et al, 2008; Pizzocaro et al, 2010). Patients with inguinal nodal metastases are at increased risk for spread to the pelvic nodes. Ravi (1993b) found no pelvic nodal metastases when inguinal nodes were negative but found positive pelvic nodes in 17 of 75 patients (22%) with one to three positive inguinal nodes and in 13 of 23 patients (57%) with more than three positive inguinal nodes. Srinivas and associates (1987) also found a similar correlation. Horenblas and colleagues (1993) showed that among patients with a single inguinal lymph node involved without extracapsular extension, the incidence of pelvic metastases was rare; they recommended avoiding pelvic dissection in such patients. Zhu and coworkers (2008) found that the sensitivity of CT for pelvic lymph node metastasis was only 37.5%. Use of the Cloquet node in predicting a positive pelvic node was only about 30% sensitive, as well. Important predictors were the number of positive nodes and lymph node size. Two contemporary studies addressing this issue have found a 0% to 12% incidence of pelvic lymph node metastasis when patients exhibited only one or two positive inguinal nodes, especially when extracapsular extension was absent and/or size was less than 3.5 cm (Lont et al, 2007; Zhu et al, 2008). Additional factors noted in these studies included the grade of the nodal metastasis and its TP53 status. Thus, patients with only a single small lymph node metastasis discovered at the time of inguinal dissection (i.e., no extracapsular extension, not high grade) may be at very low risk for pelvic metastasis and are potentially the optimal candidates in whom PLND can be avoided.

With respect to efficacy, the 5-year survival for patients with positive pelvic nodes averages around 14% (see Table 37-4). However, data from some of the smaller series suggest that in selected instances 5-year survival can occur in patients treated with surgery alone. In the series reported by Ravi (1993b), however, patients with even a single positive pelvic node did not survive 5 years (0 of 8 patients). The difficulty in determining the potential independent value of PLND as a therapeutic procedure is related to the small numbers of patients reported, the coexisting extensive inguinal adenopathy in patients with resectable pelvic nodes, and the failure to specify sites of relapse in patients undergoing IILND (i.e., inguinal versus pelvic versus distant site).

Thus, for patients undergoing ILND for curative intent (i.e., in whom preoperative studies reveal no pelvic adenopathy), PLND should routinely be considered in patients with two or more positive inguinal lymph nodes or when extracapsular nodal

extension is present. PLND in this setting serves as an effective staging tool for identifying those patients at increased risk for pelvic metastases in whom adjunctive therapy should be considered (Lont et al, 2007; Pizzocaro et al, 2010). Given the aforementioned indications, PLND can be performed simultaneously with ILND in the setting of higher volume inguinal metastases or as a secondary procedure after inguinal pathology is available. Alternatively, if pelvic nodal metastases are proven before lymphadenectomy (based on clinical findings), consideration should be given to neoadjuvant chemotherapeutic strategies followed by surgery (Leijte et al, 2007; Pagliaro et al, 2010; National Comprehensive Cancer Network [NCCN], 2012).

KEY POINTS: TREATMENT OF THE INGUINAL NODES

- The presence and extent of inguinal metastases determine survival in penile cancer.
- Patients with persistent palpable inguinal adenopathy should undergo an inguinal staging procedure.
- On the basis of the histologic features of the primary tumor, risk of lymph node metastases can be assessed in patients with no palpable adenopathy. DSNB, superficial ILND, or close follow-up can be recommended.
- Factors associated with a high cure in surgically treated patients include no more than two inguinal metastases, unilateral involvement, no ENE of cancer, and the absence of pelvic metastases. Patients with higher volumes of disease should be considered for adjuvant or neoadjuvant therapy.
- Morbidity of lymphadenectomy is decreasing in contemporary series.
- Superficial ILND reliably determines the presence of microscopic inguinal metastases without the need for specialized facilities but can have significant morbidity.
- Modified DSNB techniques to determine microscopic inguinal disease exhibit low morbidity, have been validated externally in higher-volume centers, and are now a recommended procedure in such centers.
- Laparoscopic and robotic ILND obtains lymph node yields that are comparable to those of open techniques when used in selected patients. Additional studies with larger patient numbers and longer follow-up are required before routine adoption into clinical practice.
- PLND is now recommended when more than one inguinal lymph node exhibits metastasis or when ENE of cancer is present.

Risk-Based Management of the Inguinal Region

A contemporary schema for management of the inguinal region is presented in Figure 37-4. Assumptions for these guidelines are that the primary tumor has been adequately controlled, that the pathologic stage of the primary tumor is available, and that an inguinal examination has been performed. CT of the abdomen and pelvis as well as chest radiography or other imaging studies should also be performed as clinically indicated.

Very Low-Risk Patients

Because the incidence of inguinal metastasis is anecdotal at best for patients with stage Tis or Ta primary tumors, observation is reasonable for those patients with normal inguinal examination findings (see Fig. 37-4A, left). For patients with palpable adenopathy, a course of antibiotics should reveal those whose adenopathy is related to infection versus metastasis. A persistently palpable node should undergo fine-needle aspiration cytology; if the result is negative, an excisional biopsy is recommended. If the biopsy finding is abnormal, ipsilateral inguinal dissection with contralateral

superficial or modified complete dissection is performed. DSNB is an option in experienced centers.

Low- to Intermediate-Risk Patients (American Joint Committee on Cancer Stage T1a)

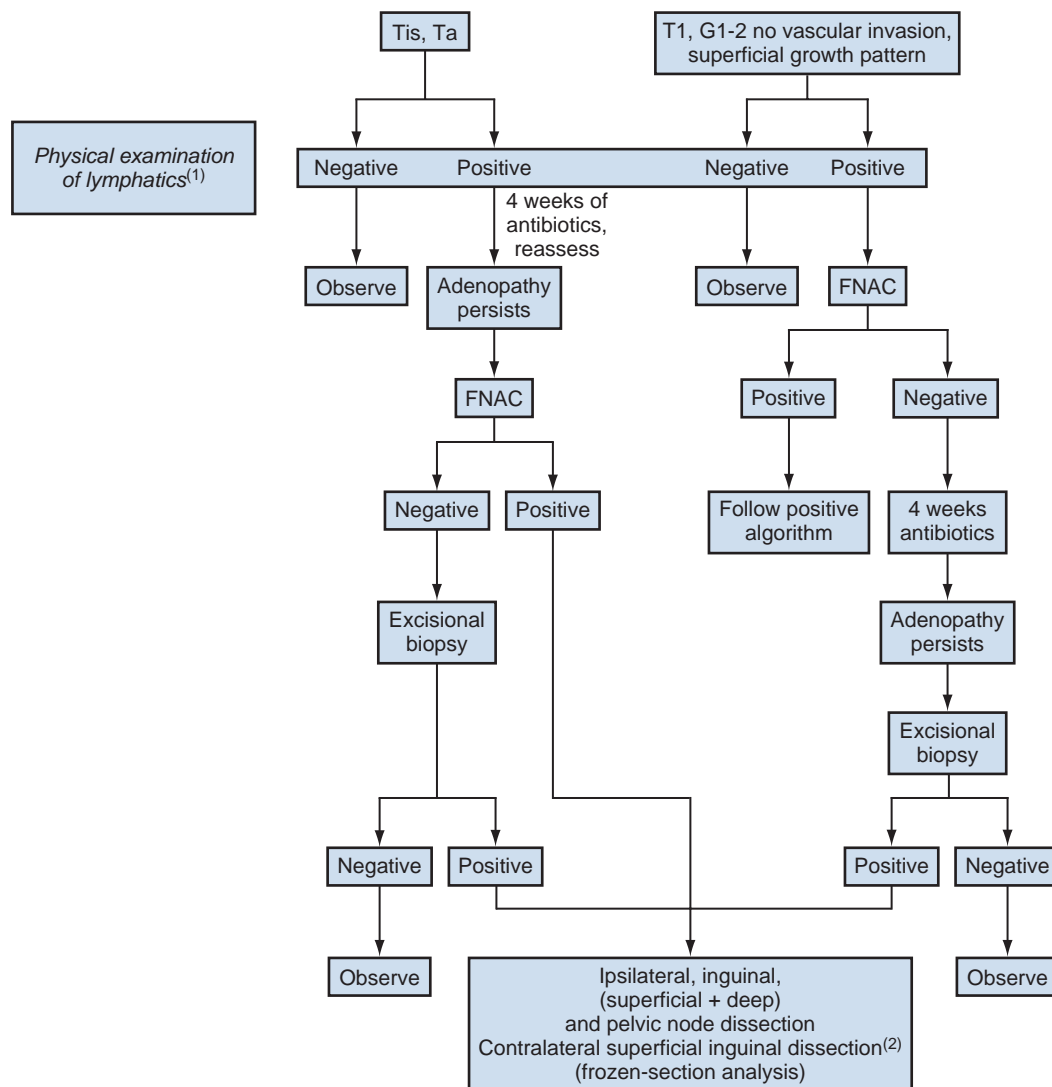

Several series have combined patients with stage T1 grade 1 and grade 2 tumors and have found them to exhibit less than a 10% incidence of inguinal metastasis (see Fig. 37-4A, right; see also Table 37-7). However, the incidence of metastasis among strictly T1 grade 2 tumors (25% to 44%) may be higher, and variable recommendations have been made. The recent EAU guidelines recommend inguinal staging for T1 grade 2 tumors (also stage T1a) among patients with clinically negative lymph nodes (Pizzocaro et al, 2010). However, observation is also an option for compliant patients in this setting (ICUD penile cancer guidelines found in Pompeo et al, 2009; NCCN penile cancer guidelines, 2012). Similar patients with palpable nodes on initial presentation should undergo fine-needle aspiration cytology. If the nodes are positive, the patients then undergo lymphadenectomy, as in Figure 37-4A. If they are negative, then a 4-week period of antibiotic therapy is reasonable. If adenopathy does not resolve, then either excisional biopsy and/or planned lymphadenectomy are reasonable options. Close

follow-up is indicated for patients whose nodes resolve after antibiotic therapy, although the overall risk in this group remains low.

High-Risk Patients (American Joint Committee on Cancer Stage T1b or Higher)

For the high-risk cohort, the incidence of inguinal metastasis ranges from 50% to 70% (see Fig. 37-4B). According to the recent guidelines, there is consensus that patients with poorly differentiated tumors, lymphovascular invasion, or pT2 or greater tumors should undergo an inguinal staging procedure (Pompeo et al, 2009; Pizzocaro et al, 2010; NCCN penile cancer guidelines, 2012). The surgical approach depicted in Figure 37-4B is designed to maximize detection and treatment for those with proven nodal metastasis while limiting the morbidity of those with negative lymph nodes at surgery. Thus surgical staging is indicated even in those patients with clinically normal inguinal examination findings. In this setting, antibiotic use minimizes the risk of inguinal wound infections or septic complications after control of an infected primary tumor, rather than influencing the decision for surgical staging.

Patients with normal inguinal examination findings are offered bilateral superficial dissection, complete modified dissection, or

(1) Includes physical examination and/or imaging studies.

A (2) Complete modified dissection and dynamic sentinel node biopsy (experienced centers) acceptable.

DSNB (with the last offered in experienced centers). If frozen-section results reveal no metastasis, the procedure is concluded. For DSNB the results are based on permanent sections; thus further therapy is planned at a second setting if needed. If either side is positive, an ipsilateral inguinal dissection is performed. Pelvic dissection in the setting of a patient with no palpable adenopathy who is discovered to have positive inguinal metastasis at frozen section is optional and based on pathologic findings (Lont et al, 2007; Zhu et al, 2008). Patients with unilateral resectable adenopathy that is strongly suggestive of metastasis should undergo an ipsilateral ilioinguinal dissection and a contralateral superficial or complete modified dissection. Frozen-section analysis then determines if deep inguinal or pelvic nodes should be excised. DSNB is another option

in managing the contralateral node-negative side. Palpable adenopathy of less than 4 cm was arbitrarily selected as a cutoff point for surgery as monotherapy because nodal metastases larger than 4 cm are associated with ENE of cancer (Ravi, 1993a).

For patients with bilateral palpable nodes that are strongly suggestive of metastasis, preoperative fine-needle aspiration cytology can be helpful for counseling of the patient as to the likelihood of the extent of surgery. For patients with negative results of fine-needle aspiration cytology, a staged surgical approach starting with superficial dissection is performed. Subsequent procedures in this setting depend on the results of frozen-section analysis. For patients requiring IILND because of metastases, adjuvant chemotherapy should be considered for those exhibiting more than two positive

lymph nodes, ENE of cancer, or pelvic nodal metastasis (Pizzocaro et al, 2010). An alternative approach to consider among patients with bilateral metastases is neoadjuvant chemotherapy followed by surgical resection as described by Pagliaro and colleagues (2010).

Bulky Adenopathy and Fixed Nodal Metastasis

Survival in patients with bulky adenopathy and fixed nodal metastasis is related to complete eradication of extensive disease (see Fig. 37-4C). This task is difficult to achieve with surgery, chemotherapy, or radiation therapy alone. The combination of surgery and chemotherapy has shown some benefit in advanced penile carcinoma (Pizzocaro et al, 1997; Corral et al, 1998; Bermejo et al, 2007; Leijte et al, 2007; Pagliaro et al, 2010). The optimal integration and timing of such therapy are unknown. A reasonable approach in this cohort of patients is to use neoadjuvant chemotherapy followed by an aggressive surgical resection for patients demonstrating either response to therapy or stable disease. The neoadjuvant approach could improve surgical resectability and avoid long delays in the administration of chemotherapy resulting from delays in postoperative healing. The prognosis is poor in patients exhibiting progression while they are receiving chemotherapy. Palliative groin dissection is a consideration but rarely provides significant palliation (Leijte et al, 2007). Hemipelvectomy in patients without distant metastases has been reported (Block et al, 1973). Endoluminal vascular stents have also been reported to have transient success in preventing vascular erosion by tumor (Link et al, 2004). Clinical trials of novel systemic strategies and radiation therapy to affected areas provide the next level of care. With further progression, supportive care provided by hospice services can provide valuable support to patients with end-stage disease.

RADIATION THERAPY

Radiation Therapy for the Primary Lesion

Primary radiation therapy has significant curative potential and may permit relative preservation of penile form and function. If local control is not achieved, salvage surgery may still be curative, and therefore in a subset of men with penile cancer radiation as an initial strategy represents a reasonable treatment strategy. Both external-beam radiotherapy and interstitial brachytherapy are currently used in treating the primary penile tumor. Before radiation therapy, circumcision is necessary to expose the lesion, to allow resolution of any surface infection, and to prevent preputial edema and subsequent phimosis.

External-Beam Radiotherapy

External-beam radiotherapy has several advantages: It is widely available, delivers a homogeneous dose, and does not require the same expertise with respect to technical skills required for delivery of effective brachytherapy. In a review, Crook and coworkers (2009) described contemporary doses and fractions as ranging from 60 Gy in 25 fractions delivered over 5 weeks to 74 Gy in 37 fractions over 7.5 weeks. This contrasts with lower doses of 50 to 55 Gy cited in older series (McLean et al, 1993; Neave et al, 1993). One of the challenges of external-beam radiotherapy is to consistently position the penis in such a way as to be accessible by the radiation beam while not implicating adjacent normal tissues and structures. This is achieved by positioning the patient supine on the treatment couch and encasing the penis in a vertical position in a block of wax or Perspex with a central cylindric chamber. The block is bivalved for ease of application, which admittedly becomes more difficult as the course of radiotherapy progresses. The second consideration involves the physical nature of megavoltage radiation beams, which spare the skin surface and deliver the radiation dose at a depth in tissue. Penile cancer is of cutaneous origin and requires full treatment of the skin surface. Wax and Perspex are both tissue-equivalent materials, so the choice of these in fabricating an immobilization device effectively boluses the penis and brings the full

dose to the skin surface. An alternative has been described, which is to treat the patient in the prone position with the penis suspended in a small waterbath container (Vujovic et al, 2001), but this is not suitable for obese patients and can be technically difficult because the penis tends to float and position itself too close to the patient's body and adjacent normal tissue.

Table 37-11 is adapted from Crook and colleagues (2009), and describes the efficacy of both external-beam radiotherapy and interstitial brachytherapy with respect to local control, cause-specific survival, complications, and penile preservation. The data represent retrospective reviews of single institution series collected over many years, during which time staging systems and treatment techniques evolved. The data thus often represent a range of doses and fractionation schemes, which permits only limited conclusions regarding optimal dose and fractionation. **Five-year local control rates among patients treated using a variety of techniques ranged from 44% to 69.7% with penile preservation rates of 50% to 65%. Thus, the ability of primary external-beam radiotherapy to control the primary tumor appears inferior to traditional surgical techniques of amputation.** However, further local control in most cases was achieved by partial or total amputation and, **more than 50% of patients treated with primary external-beam radiotherapy avoided penile amputation.** Cause-specific survival ranged from 58% to 86% depending on primary tumor stage and lymph node status.

Prognostic factors for response among patients treated with external-beam radiotherapy include dose below 60 Gy, protracted treatment time exceeding 45 days or daily fraction less than 2 Gy in addition to stage T3, size exceeding 4 cm, and high-grade tumors (Sarin et al, 1997; Gotsadze et al, 2000; Crook et al, 2009). This suggests a minimum tumor dose of approximately 66 Gy in 2-Gy fractions over a period of 6½ weeks (45 days). Hypofractionated courses (fraction size >2 Gy) may be associated with worse toxicity.

Brachytherapy

As an alternative to external-beam radiotherapy, interstitial brachytherapy using a variety of radioisotopes but most commonly iridium-192 has been reported. Gerbaulet and Lambin (1992), using percutaneously placed interstitial iridium-192 implants, reported successful local control in 82% of 109 patients, with long-term survival rates of 75% to 80% in patients with tumor-free regional lymph nodes. Rozan and associates (1995) reviewed 259 patients from multiple centers, with 5- and 10-year disease-free survival rates of 78% and 67%, respectively. Twenty-two percent of patients also had surgery ranging from circumcision or local excision (75% of procedures) to total penectomy (4%). Late side effects occurred in 53% of the group. For noninvasive or very superficial tumors, a surface mold containing iridium-192 wires can be constructed. The plastic mold is worn in close apposition to the penile shaft for 12 hours or so daily for a period of 7 to 10 days for a total tumor dose of 60 Gy (El-Demiry et al, 1984; Akimoto et al, 1997). Because the depth of tumor invasion can be difficult to ascertain by clinical examination or imaging, and because a margin of full dose (comparable to the required surgical margin) is required beyond the macroscopic disease, the mold technique is rarely appropriate. Such superficial disease may now be treated more appropriately with laser or organ-sparing surgical techniques.

Crook and associates (2009) initially reported a cohort (1989-2000) of 30 men with cT1 to cT3 squamous cell carcinoma treated with iridium-192 delivered by 17- to 19.5-gauge steel needles held in a three-dimensional parallel array by predrilled acrylic plastic templates. With a median six needles (range 2 to 9), a prescribed dose of 60 Gy (range 55 to 65 Gy) was delivered during an average of 93 hours. With a median 34 months of follow-up, there were four local failures and four regional failures, and 1 patient required partial penectomy for radionecrosis. The 2-year actuarial local failure-free rate was 85%, and successful penile conservation was 83%. Obviously, tumors could only be clinically staged, and the

authors stated that clinical distinction between cT1 and cT2 is subjective. Nodal failure related to tumor grade, but not tumor size. Kiltie and associates (2000), however, found local failures in 60% of tumors larger than 4 cm compared with 14% of tumors smaller than 4 cm. Mazon and colleagues (1984) and Soria and coworkers (1997) both demonstrated more local failure as the tumor invaded the corpora and with tumor size larger than 4 cm. In the initial Crook series, prophylactic lymph node dissections were not routinely performed, and as one would expect, 50% of moderately or poorly differentiated tumors recurred regionally or distally (Crook et al, 2002). Therefore, selection of patients for prophylactic lymph node dissection is recommended to be the same as selection of patients undergoing surgical removal of the primary tumor.

The Crook series was updated in 2009 to 67 patients with a median follow-up of 4 years (range 0.2 to 16.2). At 10 years the

actuarial cause-specific survival was 83.6%, and three late failures were observed (42, 64, 90 months). Penectomy was performed for 8 recurrences and 2 necroses for 5- and 10-year penile preservation rates of 88% and 67%, respectively. Inguinal lymph nodes in the most recent patients were managed with the same indications as for patients undergoing primary surgery, but with use of only biopsy information for determining high-grade disease and the presence of lymphovascular invasion. One predictor of local failure in this series was needle spacing—an increase in spacing (range 12 to 18 mm) decreased recurrences because of the wider lateral margin achieved. Overall, local control (see Table 37-11) provided by interstitial brachytherapy appeared superior to that provided by external-beam radiotherapy, with 5-year local control rates of 70% to 87%. Penile preservation rates are highest at 5 years (74% to 88%), with some decrease at 8 to 10 years (67% to 70%) (Crook et al, 2009).

Adverse Effects Associated with Radiotherapy

Acutely, after radiotherapy or brachytherapy one can expect moist desquamation at the treated site. This will be more extensive after external-beam radiotherapy because of the larger treatment volume. Re-epithelialization occurs in 4 to 8 weeks. Saline soaks and hygiene are important. Intercourse can be resumed when the patient is comfortable, but the use of additional water-based lubrication is recommended.

The two most common late side effects associated with radiotherapy are **meatal stenosis and soft-tissue ulceration**. Earlier series (from the 1960s to early 1970s) reported urethral fistula, stricture, or stenosis, with or without penile necrosis, pain, and edema (Kelley et al, 1974), in some instances necessitating secondary penectomy (Duncan and Jackson, 1972). Soft-tissue ulceration overall is reported in 0% to 23% of patients treated with external-beam or interstitial radiotherapy, with the higher rates associated with brachytherapy (see Table 37-11). In the case of persistent ulceration, a diagnostic dilemma exists in determining whether recurrent cancer is present; biopsy may be indicated. In general, ulceration is flat and superficial, with no raised or exophytic component. Close follow-up and treatment with antibiotics, vitamin E, and steroid creams are recommended. For cases resistant to these measures, a course of hyperbaric oxygen is often effective (Crook et al, 2009; Gomez-Iturriaga et al, 2011). The majority will heal with conservative management, but healing may take several weeks, and longer in diabetic patients. The more deeply invasive the original tumor, the longer healing can take. Meatal stenosis is reported in 10% to 45% of patients and may be related to increased dose per fraction in those treated with external-beam radiotherapy or needle spacing among those treated with brachytherapy. Meatal stenosis occurs later in follow-up (18 to 24 months) and may often be preceded by report of a weak, deviated or divided urinary stream. Intervention at this time using a meatal dilator will help to prevent subsequent unyielding fibrotic stenosis. Patients can be taught to do this themselves as required. If not appropriately managed, urethral strictures may occur late and may require a more formal dilation or, in very rare cases, urethroplasty.

The benefits of avoiding a mutilating surgical procedure are obvious, and although sexual function is typically reported to be preserved, the side effects of radiation on sexual quality of life have not been studied with validated instruments (Crook et al, 2009). Because brachytherapy irradiates much less of the penile shaft and erectile tissue, erectile function is more likely to be preserved than after external-beam radiotherapy. Patients and physicians must carefully consider the unique acute and long-term side effects of radiation therapy. For the elderly in whom sexual function is not an issue, partial penectomy may be quite acceptable, offering a prompt and effective treatment with relatively few side effects limiting activity in the postoperative period.

The organ-sparing benefits of radiation now must be compared with surgical choices such as laser therapy, Mohs micrographic surgery, and reconstructive surgery, all of which can provide organ sparing while minimizing functional loss. This emphasizes the need for multidisciplinary assessment and tertiary referral to centers where all options are available. Radiation may be the only solution for a patient with significant comorbidities who is not a surgical candidate.

Finally, as with any organ-sparing approach, extended follow up is essential. This must be emphasized to the patient at the time of the original treatment decision. Teaching self-examination and prompt reporting of concerns is also important. Local recurrence can be salvaged surgically without jeopardizing survival. Careful long-term follow-up is essential to detect recurrence promptly, and it must be recognized that recurrence may develop relatively late. In one series, 7 of 11 recurrences were detected after 2 years (63%) and 2 (18%) after 5 years (Mazon et al, 1984). In terms of salvage surgery, Crook et al (2009) noted that external-beam radiotherapy typically treats much more of the penile shaft, whereas brachytherapy is more focal, leading to salvage options that are more likely to result in a partial penectomy than a total penectomy.

In summary, T1 and T2 tumors smaller than 4 cm with no or minimal extension beyond the coronal sulcus respond well to radiotherapy, and with careful planning, complications can be minimized (de Crevoisier et al, 2009). Brachytherapy can provide good local control and penile preservation with faster dose delivery (4 to 5 days rather than 6 to 7 weeks) compared with external-beam radiotherapy. For the patient who is an appropriate candidate for a radiation-based approach, the selection of external-beam radiotherapy versus brachytherapy may depend on the skill and experience of the radiation oncologist involved; external-beam radiotherapy may be more widely available. Crook and colleagues' series and review (2009) would suggest that the brachytherapy technique should be expanded and studied further in a multi-institutional fashion.

The treatment of locally advanced disease is clearly associated with a higher failure rate (local, regional, and distant), and the treatment approach must take into consideration regional nodes. For these patients, brachytherapy is not an option. Combined chemoradiotherapy radio sensitizers like cisplatin weekly—standard management in squamous carcinoma of the cervix—is well tolerated, is associated with excellent response rates, and may convert a patient with inoperable disease into a surgical candidate or alternatively may be used as definitive management (Rose, 2002). This approach will be studied in a cooperative international trial run through the International Rare Cancers Initiative (Nicholson et al, 2014).

Radiation Therapy for the Inguinal Areas

The presence and extent of lymph node involvement is such a key prognostic factor in the management of penile cancer that surgical evaluation of the inguinal regions is widely accepted. Surgical evaluation of high-risk, clinically node-negative patients is recommended so that additional treatment can be tailored to the actual pathology, rather than just offering "prophylactic" radiation to the inguinal nodes. A surgical approach to resectable adenopathy is also preferable because a dose that is sufficient to sterilize macroscopic disease in the groins is poorly tolerated (Murrell and Williams, 1965; Jensen, 1977; Kulkarni and Kamat, 1994). Furthermore, assessment of the treatment of the inguinal area by primary radiation therapy is hampered by the uncertainty arising from the inaccuracy of clinical staging and the frequent lack of histologic confirmation of nodal metastases. Table 37-3 summarizes the incidence of node positivity in clinically negative groins and suggests that radiation can be avoided in the majority of cases.

One of the largest series demonstrating a benefit of radiation therapy for lymph node metastases and/or distant metastases from penile cancer was published by Ravi and associates in 1994. One hundred and twenty patients with lymph node metastases and 9 with distant metastases were managed by radiation therapy alone (palliative) or in the preoperative or postoperative setting. Pertinent to the advanced disease presentation setting, 33 patients were treated with preoperative radiation therapy at 40 Gy over 4 weeks and subsequently had ILND. Of note, after radiation therapy and surgery, only 8% had evidence of ENE, and 3% recurred within the groin. This is relevant because in a prior report within a contemporary time frame (Ravi, 1993a), the incidence of ENE was 33% among patients treated with surgery alone, and groin recurrence was noted in 19%. The differences for both ENE and local recurrence were statistically lower ($P < .01$ and $P < .03$, respectively). The data are suggestive but not definitive that preoperative radiation therapy for nodes 4 cm or larger without skin fixation improved local control. The 5-year survival among the latter group was 70% (Ravi et al, 1994). These data are consistent with the beneficial effects seen when radiotherapy is used together with surgery or chemotherapy in other squamous malignancies such as vulvar, cervical, or anal carcinomas (Epidermoid anal cancer, 1996; Montana et al, 2000; Green et al, 2001). Such approaches should be further explored in the treatment of locally advanced penile cancer.

In the series by Ravi and colleagues (1994), palliative radiation therapy ameliorated symptoms in 56% of patients with fixed groin

nodes, in 5 of 5 patients with painful bony metastases, and in 1 of 2 patients with spinal cord compression and paraplegia. However, pelvic and/or para-aortic radiation therapy was ineffective in patients with pelvic node metastases. Thus radiation therapy may be considered in patients with inoperable fixed and ulcerative inguinal lymph nodes who are not candidates for chemotherapy. On occasion, radiation to these areas is well tolerated, may result in significant palliation, and may postpone local complications for prolonged periods (Furlong and Uhle, 1953; Staubitz et al, 1955; Vaeth et al, 1970). Combined chemoradiotherapy is a promising approach, as previously mentioned, using weekly cisplatin as is successful in squamous carcinoma of the cervix (Rose, 2002).

Radiation has an important role to play as adjuvant therapy for surgically treated, pN+ patients. In a small retrospective study from Taiwan, Chen and colleagues (2004) reported regional failure rates after positive inguinal lymph node dissections in 11% (1 of 9) versus 60% (3 of 5) with and without adjuvant inguinal radiotherapy. Extrapolating from the published literature on vulvar cancer (Hyde et al, 2007), adjuvant radiotherapy 4500 cGy in 25 fractions over 5 weeks to the ipsilateral groin should be considered for patients with more than two positive nodes and for those with ENE. If the pelvic nodes are known to be clear, then the pelvis need not be included; but if pelvic node dissection has not been performed, then the radiation volume should extend to include the pelvis.

In summary, radiation therapy to the inguinal area is not recommended as prophylaxis for patients at high risk for inguinal node metastases. It is less effective therapeutically than a lymph node dissection for clinically involved nodes but should be considered as adjuvant treatment for those with more than two nodes positive or ENE. It may be useful for palliation in the situation of inoperable nodes and in a chemoradiotherapy approach may render inoperable disease resectable. Based on studies in other squamous malignancies, radiation as a part of a multimodal approach with chemotherapy and surgery among patients with advanced penile cancer should be further evaluated.

KEY POINTS: RADIATION THERAPY

- Primary radiation therapy for penile cancer may be successfully applied to select patients with T1 and T2 squamous cell carcinomas smaller than 4 cm with either external-beam radiotherapy or brachytherapy techniques.
- Salvage penectomy may be required after external-beam radiation or brachytherapy for persistent or recurrent disease or radiation necrosis. Lifelong careful follow-up is required.
- For patients selected for radiation therapy for the primary tumor, surgical management of inguinal lymph nodes should be recommended by the same criteria as for patients selected for surgical management of the primary tumor.
- Radiation to the inguinal area is not as effective as surgery for treatment of the inguinal nodes.
- Prophylactic radiotherapy has not been shown to alter the natural history of inguinal metastases and is not recommended.
- Integration of radiotherapy with surgery and chemotherapy in advanced disease requires further study.
- Palliative radiotherapy among patients with inoperable inguinal nodes may provide some benefit.

CHEMOTHERAPY

Advanced penile cancer manifesting as either bulky or unresectable regional disease or visceral metastases at initial presentation or disease recurrence is highly lethal because it is incurable in most cases with either surgery or radiotherapy alone (Ornellas et al, 1994; Ravi et al, 1994; Hegarty et al, 2006). Experience with single-agent or multiagent chemotherapy in this setting is limited because there are few phase 2 clinical trials and no randomized clinical trials. Several regimens have produced clinically meaningful

responses that have occasionally resulted in clearance of disease or facilitated surgical resection.

Single-Agent Chemotherapy

Gagliano and associates (1989) from the Southwest Oncology Group treated 26 patients, 12 of whom had received prior radiation, with low-dose (50 mg/m²) cisplatin, and observed a 15% response rate of 1 to 3 months' duration and a median overall survival of 4.7 months. In a study from Memorial Sloan Kettering Cancer Center, 13 patients with extensive disease and either prior radiotherapy or chemotherapy were treated with cisplatin 70 to 120 mg/m² every 21 days. Three of 12 evaluable patients (25%) demonstrated responses (1 complete and 2 partial; duration 2 to 8 months; Ahmed et al, 1984).

Initial favorable reports from Japan suggested that bleomycin appeared to be effective in the treatment of penile and scrotal cancer. Ichikawa and associates reported a 50% response in 24 previously untreated patients with squamous carcinoma of the penis (Ichikawa et al, 1969; Ichikawa, 1977). A similar report from Uganda documented partial or complete tumor regression in 45% of treated patients (Kyalwazi et al, 1974). A review of 90 patients from the world literature demonstrated similar responses (Eisenberger, 1992). In a study by Ahmed and colleagues (1984), 14 patients were evaluable for response to single-agent bleomycin. There was one complete response, but the patient died from bleomycin pulmonary toxicity. There were also two partial responses, for an objective response rate of 21%. The median response duration was only 3 months (range 2 to 4).

Methotrexate produced responses in 8 of 13 patients (61%) treated at Memorial Sloan Kettering Cancer Center (Ahmed et al, 1984) with one complete response. However, median response duration even with the high response rate was 3 months (2 to 31 months), and one patient died from treatment-related sepsis. Methotrexate had been shown to be active in other reports (Mills, 1972; Garnick et al, 1979). Based on the Ahmed study, in which cisplatin, bleomycin, and methotrexate were given sequentially, there did not appear to be any obvious cross-resistance to the three agents. Subsequently a three-drug trial using cisplatin, bleomycin, and methotrexate was developed.

Combination Chemotherapy

The Southwest Oncology Group reported a phase 2 study using a modified regimen that reduced the total dose of cisplatin, bleomycin, and methotrexate. Haas and associates (1999) employed combination cisplatin, methotrexate, and bleomycin in 45 patients with locally advanced or metastatic penile cancer accrued from 31 different institutions. There were five complete and eight partial responses among 40 evaluable patients (32.5% response rate). The median duration of response was 16 weeks with an overall survival of 28 weeks (Haas et al, 1999). Although the response rate appeared encouraging, it was still within the 95% confidence interval (CI) for single-agent cisplatin, and there were five treatment-related deaths in the study (one from infection and four from pulmonary complications) (Ahmed et al, 1984; Gagliano et al, 1989; Haas et al, 1999). Thus this study failed to confirm the initial high response rate of single-agent methotrexate; the response rate was not significantly higher than that of single-agent cisplatin, and bleomycin pulmonary toxicity was significant (Haas et al, 1999).

Three additional contemporary trials, all including cisplatin, revealed significant activity while omitting the bleomycin and methotrexate. Theodore and colleagues (2008) reported the results of a European Organisation for Research and Treatment of Cancer (EORTC) phase 2 study in which 28 patients with locally advanced or metastatic disease (T3, T4, N1 to N3, or M1) received combination cisplatin and irinotecan. Patients were treated in either the neoadjuvant setting for four cycles before surgery (T3, N1 or N2) or up to eight cycles (T4, N3, M1 disease). Toxicity was acceptable, with no treatment-related deaths. Eight responses were noted (two complete, six partial) for an objective response rate of 30.8% (80%

CI 18.8% to 45%). Of note, three patients taken to surgery in the neoadjuvant setting were found to have no evidence of residual disease. The authors reported the trial as negative, however, because it was powered to show an objective response rate not less than 30% by CI.

A phase 2 clinical trial of neoadjuvant paclitaxel, ifosfamide, and cisplatin chemotherapy (TIP) was conducted at the University of Texas MD Anderson Cancer Center (Pagliaro et al, 2010). Eligible patients had stage Tx, N2 or N3 lymph node metastases, no evidence of distant metastases (M0), and no prior chemotherapy. Treatment consisted of four courses of TIP followed by bilateral inguinal lymph node dissections, unilateral or bilateral pelvic lymph node dissections, and surgical control of the primary tumor when appropriate. The objective response rate was 50% (15 of 30 patients), and the pathologic complete response rate was 10% (3 patients). Twenty-three patients completed four courses of TIP, and 22 of those underwent surgery. Nine patients (30% for the trial, 40.9% of those completing treatment) were alive and disease free at a median follow-up of 34 months. Nineteen deaths occurred as a result of progressive disease, and 2 from unrelated causes. Toxicity was acceptable and no treatment-related deaths occurred (Pagliaro et al, 2010). Thus the data for use of the TIP regimen suggest a response rate that may be significantly higher than that of single-agent cisplatin and better tolerance than with prior bleomycin- or methotrexate-containing regimens. Table 37-12 provides safety and efficacy data for cisplatin-containing chemotherapy regimens reported thus far. Treatment-related pulmonary toxicity and death were avoided with the absence of bleomycin.

A third prospective trial evaluated the combination of docetaxel, cisplatin, and 5-fluorouracil (TPF) in patients with locally advanced or metastatic penile cancer (Nicholson et al, 2013). The objective response rate was 38.5% (10 of 26 evaluable patients), and 65.5% of patients experienced at least one grade 3 or grade 4 event. The predetermined target response rate of 60% was not reached, and the authors concluded that similar results could be achieved with 5-fluorouracil and cisplatin and that the addition of docetaxel resulted in toxicity. The objective response rate to 5-fluorouracil and cisplatin in one retrospective series was 32% (8 of 25 patients) (Di Lorenzo et al, 2012).

Data from the aforementioned three prospective trials and one retrospective series suggest that patients with advanced, unresectable primary tumors or metastatic disease can benefit from cisplatin-based chemotherapy, and selected patients with bulky regional lymph node metastases appeared to benefit from post-chemotherapy lymphadenectomy. Negative pathology in lymph nodes was seen after neoadjuvant treatment with TIP (3 of 30 patients) and irinotecan and cisplatin (3 of 7 patients). For patients

with unresectable primary tumors or bulky regional lymph node metastases, neoadjuvant treatment with a cisplatin-containing regimen may be effective and may allow curative resection. The optimal chemotherapy regimen has yet to be determined.

Adjuvant Chemotherapy

Historically, combination vincristine, bleomycin, and methotrexate therapy was administered in 12 weekly courses to 17 patients in the postoperative setting (12) or neoadjuvant setting (5) at the Milan National Tumor Institute. The patients treated were at high risk for recurrence with surgery alone; 9 showed extranodal tumor growth, 5 had pelvic nodal involvement, and 5 had bilateral metastases. At follow-up ranging from 18 and 102 months, only 1 relapse had occurred (Pizzocaro and Piva, 1988). Later, reports from this center further confirmed the value of adjuvant chemotherapy. Of 56 node-positive patients, 82% of the 25 patients receiving adjuvant vincristine, bleomycin, and methotrexate therapy survived 5 years, compared with 37% of 31 patients treated with surgery alone (Pizzocaro et al, 1995, 1997). In the neoadjuvant treatment group, partial responses were noted in 3 of 5 patients with extremely large (6 to 11 cm) nodal metastases. These three patients subsequently were completely resected and were free of tumor at intervals ranging from 20 to 72 months. These data have yet to be confirmed and will probably not be further studied, given the potential toxicities of bleomycin and methotrexate.

Postchemotherapy Surgical Consolidation

Shammas and colleagues (1992) reported on eight patients treated with the combination of cisplatin and 5-fluorouracil. Seven of the eight patients had Jackson stage III or IV disease, and two in this group had either pleural or lung metastases. One of 7 (14%) had a partial response with disappearance of lung metastases and post-surgical consolidation and lived for longer than 32 months. He received five cycles of therapy. Three patients with stable disease received only one or two cycles and survived for 2 or more to 11 months. Of note, two of three patients who ultimately had disease progression received three or four cycles of therapy and underwent surgical consolidation with survival times of 12 and 28 months from chemotherapy.

Thus, 2 of 7 patients (28%) who survived 28 and more than 32 months received significant palliation or cure from the combination. Corral and coworkers (1998) reported on the long-term follow-up of a prospective group of patients treated with bleomycin, methotrexate, and cisplatin. Among the cohort, 21 patients had penile carcinoma, with 10 of 21 (48%) having either N3 or M1

TABLE 37-12 Safety and Efficacy of Multidrug Penile Cancer Regimens without Bleomycin

	CHEMOTHERAPY	RESPONSE RATE	TREATMENT-RELATED DEATH	MEDIAN OVERALL SURVIVAL (mo)

disease. The remainder had either N1 or N2 nodal metastases. Objective responses were noted in 12 (57%), including 2 of 5 with distant metastases. Six patients in the group (28.5%) achieved disease-free status with either chemotherapy alone (2) or surgery (3) or radiation therapy (1) with a median survival of 27.8 months. This was significantly longer than in those not achieving disease-free status (6.7 months, $P = .004$). Thus, this prospective study showed that a multidisciplinary approach to achieve disease-free status could prolong survival. Subsequently [Leijte et al \(2007\)](#) from the Netherlands Cancer Institute reviewed their experience with neoadjuvant chemotherapy in patients with initially “unresectable” penile cancer. The series included 20 patients treated with five different regimens including (1) single-agent bleomycin; (2) bleomycin, vincristine, and methotrexate; (3) cisplatin and 5-fluorouracil; (4) bleomycin, cisplatin, and methotrexate; and (5) cisplatin and irinotecan. The objective responses were evaluable in 19 (1 patient died because of bleomycin toxicity after 2 weeks), with 12 responses (63%, 2 complete, 10 partial). Surgical procedures included treatment of the primary tumor as well as inguinal and pelvic dissections. Additional soft-tissue resection including bone was sometimes required. Vascularized tissue flaps were used for inguinal reconstruction. Among 12 responders, only 9 went to surgery because 2 died of bleomycin-related complications and a third was deemed unfit for surgery. Eight of 9 responding patients taken to surgery (2 were pT0) were free of disease with a median follow-up of 20.4 months. This is in contrast to 3 nonresponders who went to surgery for palliative intent. All 3 died within 4 to 8 months as a result of locoregional recurrence. The implications of this study are that response to chemotherapy together with an aggressive surgical procedure provides the optimal scenario for significant palliation or potentially cure.

In a separate study [Bermejo et al \(2007\)](#) described the surgical considerations and complications among 10 patients who had either a response or stable disease after combination chemotherapy. The regimens included (1) bleomycin, methotrexate, and cisplatin; and (2) paclitaxel, ifosfamide, and cisplatin (TIP), or (3) paclitaxel and carboplatin. This cohort of patients exhibited bulky inguinal or pelvic metastases, with the only exclusions being patients with fixed pelvic masses or complete encasement of the femoral vessels. In addition to IILND, resection of the inguinal ligament, the inferior aspect of the rectus abdominis or external and internal oblique muscles, the spermatic cord and ipsilateral testicle, and segments of the femoral artery and vein (with subsequent patch or bypass grafting) was performed to achieve negative margins. Plastic surgery consultation was obtained for wound coverage, including the insertion of monofilament polypropylene mesh for abdominal wall defects and myocutaneous flaps of the sartorius, rectus abdominis, serratus anterior, and latissimus dorsi muscles. Among 5 patients exhibiting an objective response, 3 were alive and disease free at 48, 50, and 73 months. Two other patients died (1 of disease at 30 months, another of unknown causes at 21 months). Among the 5 remaining patients with stable disease, 3 were dead of disease within 7 months and 1 patient treated with bleomycin died of “failure to thrive” at 8 months. However, another patient treated with paclitaxel and carboplatin who achieved only stable disease was alive and disease free at 84 months. These data appear to reinforce the concept that response to systemic chemotherapy before surgery enhances the chance for long-term survival among those undergoing surgical resection. Related to systemic therapy, the authors reported that the TIP regimen was well tolerated and all three pT0 responses at surgery were among patients treated with TIP. This provided the rationale for the prospective phase 2 study discussed previously ([Pagliaro et al, 2010](#)). In that study, the patients with response to neoadjuvant TIP had significantly better overall survival ($P = .001$) and time to progression ($P < .001$) compared with those who did not.

Taken together, these data provide evidence that response to chemotherapy improves resectability and survival. Surgery among patients who do not respond to therapy may occasionally be associated with long-term survival but is more often associated with death because of either rapidly occurring locoregional recurrence or

distant metastases ([Bermejo et al, 2007](#); [Leijte et al, 2007](#); [Pagliaro et al, 2010](#)).

KEY POINTS: CHEMOTHERAPY

- Treatment with a cisplatin-containing regimen in advanced metastatic penile cancer should be considered because responses do occur and this may facilitate curative resection. The optimal chemotherapy regimen has yet to be determined.
- The use of bleomycin in the treatment of men with penile cancer was associated with an unacceptable level of toxicity and is discouraged as first-line therapy.
- Surgical consolidation to achieve disease-free status or palliation should be considered in fit patients with a proven objective response to systemic chemotherapy.
- Among patients whose tumor progresses through chemotherapy, surgery is not recommended.

NONSQUAMOUS PENILE MALIGNANT NEOPLASMS

Nonsquamous penile malignant neoplasms are extremely rare. Pathologic descriptions and local and regional treatment options are available; however, outcomes and comparisons are limited to case reports and small retrospective series. Most reports establish the following features: (1) incidence of disease, (2) distinguishing pathologic features, (3) treatment recommendations, and (4) parallels (or lack thereof) to the same carcinoma in nongenital locations.

Basal Cell Carcinoma

Although basal cell carcinoma is frequently encountered on other sun-exposed cutaneous surfaces, it is rare on the penis ([Fig. 37-5A](#)). Fewer than 30 cases have been well documented ([Goldminz et al, 1989](#); [Ladocsi et al, 1998](#); [Nguyen et al, 2006](#)). The lesion can be seen anywhere on the penis but is commonly on the penile shaft. It is slow growing, and delay in diagnosis in one series ranged from 2 months to 50 years ([Kim et al, 1994](#)). Treatment is by local excision, which is virtually always curative ([Hall et al, 1968](#); [Goldminz et al, 1989](#)). Only one case report describes what the authors believe to be the only reported case of metastatic penile basal cell carcinoma ([Jones et al, 2000](#)). [Nguyen and colleagues \(2006\)](#) reported two cases of basal cell carcinoma treated by Mohs surgery.

A benign variant of basal cell carcinoma, the premalignant fibroepithelioma of Pinkus, has been reported to occur on the penile shaft ([Heymann et al, 1983](#)). Diagnosis is made at excisional biopsy. Excision has been uniformly curative.

Melanoma and basal cell carcinoma rarely occur on the penis, presumably because the organ's skin is protected from exposure to the sun. Malignant neoplasms arising from the supporting structures of the penis are also rare and include any combination of tumors of smooth or striated muscle or of fibrous, fatty, or vascular tissue. Information about appropriate treatment of these malignant neoplasms is derived from the review of single case reports and small series ([Belville and Cohen, 1992](#)).

Melanoma

More than 150 cases of melanoma of the penis have been reported ([Fig. 37-5B](#)). Of 1200 melanomas treated at Memorial Sloan Kettering Cancer Center, only 2 were of penile origin ([Das Gupta and Grabstald, 1965](#)). At the University of Texas MD Anderson Cancer Center, less than 1% of all primary penile cancers were malignant melanomas ([Johnson and Ayala, 1973](#); [de Bree et al, 1997](#)).

Melanoma manifests as a blue-black or reddish brown pigmented papule, plaque, or ulceration on the glans penis. It occurs on the prepuce less frequently. Diagnosis is made by

Figure 37-5. Clinical examination findings from non-squamous cell carcinomas involving the penis. **A**, Basal cell carcinoma. **B**, Melanoma. Note superficial spreading melanoma (*large arrowheads*), melanoma in situ (*arrow*), and two areas of possible melanosis (*small arrowheads*). **C**, Leiomyosarcoma (*arrows*). **D**, Paget disease. **E**, Paget disease after resection.

histologic examination of biopsy specimens, which demonstrate atypical junctional cell activity with displacement of pigmented cells into the dermis.

Prognostic characteristics that have been found significant for melanoma in other sites, such as depth of invasion (Clark staging) and thickness of the tumor (Breslow classification), have not been prospectively applied to penile lesions because experience with these lesions is limited. [Sanchez-Ortiz and colleagues \(2005\)](#) used the AJCC system for classifying cutaneous melanomas ([Fleming, 1997](#)) in the largest report to date on melanomas of the penis. This system incorporates elements of the Clark and Breslow staging systems. When this information is favorable, local excision is feasible. Distant metastatic spread has been found in 60% of patients studied ([Abeshouse, 1958](#); [Johnson et al, 1973](#); [de Bree et al, 1997](#)) in older series. However, Sanchez-Ortiz found that patients with early-stage melanomas had excellent outcomes if primary tumors were of low stage and regional lymph nodes were negative. Hematogenous metastases occur by means of the vascular structures of the corporeal bodies; lymphatic spread to the regional inguinal and pelvic nodes occurs by lymphatic permeation.

Surgery is the primary mode of treatment; radiation therapy and chemotherapy are of only adjunctive or palliative benefit. For stage I melanoma (localized lesion without metastases) and stage II melanoma (metastases confined to one regional area), adequate excision of the primary tumor by partial or total penile amputation together with en bloc bilateral ilioinguinal node dissection has historically been advocated ([Johnson et al, 1973](#); [Bracken and Diokno, 1974](#); [Manivel and Fraley, 1988](#)). In reviewing the University of Texas MD Anderson Cancer Center experience plus the literature to date, [Sanchez-Ortiz and colleagues \(2005\)](#) proposed a treatment algorithm for management of the primary tumor and

inguinal lymph nodes. For tumors of the foreskin, circumcision may be adequate. For glans tumors, a partial penectomy was recommended; and for glans-shaft tumors, a partial or total penectomy can be performed. The authors recommend bilateral modified inguinal lymph node dissections in all patients with lesions that are Breslow depth 1 mm or greater, with ulceration, or with Clark level IV or V involvement. Although dynamic sentinel lymph node biopsy techniques are increasingly used in more common sites of melanoma, their use in penile melanoma is unproven as yet. This is likely because of the rarity of the disease ([Sanchez-Ortiz et al, 2006](#)).

The prognosis for patients with penile melanoma is clearly dependent on stage of the primary tumor and the presence or absence of inguinal metastases. Contemporary staging and prognostic factors were reviewed by [Sanchez-Ortiz and coworkers \(2005\)](#). A report from the Netherlands ([van Geel et al, 2007](#)) focused on the concept of mucosal site penile melanomas—glans, meatus, fossa navicularis, and distal urethral. These lesions may appear more aggressive than cutaneous lesions, but greater delay in diagnosis may be a factor. In a pooled, retrospective analysis of 66 cases, the recurrence outcomes were similar for cutaneous melanomas of comparable tumor thickness.

Sarcomas

Primary mesenchymal tumors of the penis are rare. A thorough review of 46 such tumors from the Armed Forces Institute of Pathology revealed an equal number of benign and malignant lesions ([Dehner and Smith, 1970](#)). The patients ranged in age from newborn to the eighth decade of life. The presenting signs and symptoms of subcutaneous mass, penile pain and enlargement, priapism, and

urinary obstruction were the same for both benign and malignant lesions. A sarcoma has been reported to masquerade as a Peyronie plaque (Moore et al, 1975).

Malignant lesions were found more frequently on the proximal shaft (Fig. 37-5C); benign lesions were more often located distally. The most common malignant lesions were those of vascular origin (hemangioepithelioma), followed in frequency by those of neural, myogenic, and fibrous origin (Ashley and Edwards, 1957). Single case reports of sarcomatous lesions have been published—for example, malignant fibrous histiocytoma (Parsons and Fox, 1988), angiosarcoma (Rasbridge and Parry, 1989), leiomyosarcoma (Planz et al, 1998), epithelioid sarcoma (Leviav et al, 1988), hemangioendothelioma (Kamat et al, 2004), and osteosarcoma (Sacker et al, 1994).

Sarcomas have been classified as superficial when they arise from the integumentary supporting structures and as deep when they develop from the corporeal body supporting structures (Pratt and Ross, 1969). Wide, local surface excision and partial penile amputation for the superficial tumors have been suggested and used successfully in isolated case reports (Pak et al, 1986; Dalkin and Zaontz, 1989). Total penile amputation has been reserved for tumors of deep corporeal origin. However, local recurrences are characteristic of sarcomas (Dehner and Smith, 1970). Fetsch and colleagues (2004), from the Armed Forces Institute of Pathology, have updated their series of 14 cases of leiomyosarcoma with review of the literature. They concluded that small lesions (smaller than 2 cm) were best managed with local resection, whereas deeper-seated tumor often necessitates partial or total amputation. Deep lesions at the base of the penis have the worst prognosis.

Regional metastases are rare. Unless adenopathy is palpable, node dissections are not recommended (Hutcheson et al, 1969). Distant metastases have also been unusual (Dehner and Smith, 1970). This supports aggressive local treatment in anticipation of cure. Radiation therapy and chemotherapy have not been used extensively enough for comment on their efficacy (Fetsch et al, 2004).

Kaposi sarcoma, which is usually a cutaneous manifestation of a generalized lymphoreticular disorder, may produce genital lesions but is now most frequently associated with HIV infection.

Extramammary Paget Disease

Extramammary Paget disease (EMPD) of the penis is rare, with fewer than 30 cases reported (Mitsudo et al, 1981; Macedo et al, 1997) up to the late 1990s. However, more recently several larger series have been reported from China and Korea (Yang et al, 2005; Wang et al, 2008). It appears grossly as an erythematous, eczematoid, well-demarcated area that cannot be clinically distinguished from erythroplasia of Queyrat, Bowen disease, or carcinoma in situ of the penis. Clinical presentation includes local discomfort, pruritus, and occasionally a serosanguineous discharge involving the penis, the scrotum, or even the perianal area (Fig. 37-5D and E). On microscopic examination, identification is clearly made by the presence of large, round or oval, clear-staining hydropic cells with hypochromatic nuclei (i.e., Paget cells). The cells often stain positively for cytokeratin 7 in addition to carcinoembryonic antigen and show gross cystic fluid protein but are S-100 protein negative (O'Connor et al, 2003). The tumor behaves as a slow-growing intraepithelial adenocarcinoma with cells derived from apocrine glands. With time the cells may become invasive with dermal tumor deposits metastasizing to regional lymph nodes via dermal lymphatics (Park et al, 2001; Hegarty et al, 2011). Of note, penoscrotal EMPD may be associated with other malignancies of the genitourinary tract, such as prostate, bladder, and renal malignancies (Chanda, 1985; Ojeda et al, 1987; Koh, 1995; Allan et al, 1998), and should be evaluated for their presence. In a recent series from MD Anderson Cancer Center among 20 reported patients, 9 (45%) had at least one other malignancy including prostate, bladder, renal, skin, esophageal, and rectal sites. Of note, 8 of the 9 patients were diagnosed with the other cancer before their diagnosis of EMPD.

Two reports from the Far East have added to the case series in the literature: 130 cases of penoscrotal Paget disease from China (Wang et al, 2008) and 36 from South Korea (Yang et al, 2005). In most cases only the skin and dermis must be resected with a gross margin of up to 3 cm. Positive margins may still occur, and frozen sections are recommended to guide the extent of resection. Local skin or scrotal flaps (Wang et al, 2008) can be used to cover the defects. Patients with a positive surgical margin are at a higher risk for recurrence, and additional resection is advised. In the series from Hegarty et al (2011), no recurrences were noted among patients with intraepidermal EMPD with negative surgical margins.

In a minority of cases the tumor may invade deeper structures, necessitating more extensive resection and reconstruction, as reported in case series (Hatoko et al, 2002; Fujisawa et al, 2008). If inguinal adenopathy is present, radical node dissection is advised (Hagan et al, 1975) but prognosis is poor (Yang et al, 2005). Hegarty and colleagues (2011) described the use of neoadjuvant docetaxel and carboplatin chemotherapy and surgical resection in two patients. One patient was alive with disease at 40 months, and the other had no evidence of disease at 13 months.

Adenosquamous Carcinoma

Adenosquamous carcinoma is a rare tumor characterized by both glandular and squamous histologic elements that are independent of the urethral glands. It manifests as a large (5 to 9 cm), firm, and grayish white granular exophytic mass involving the distal shaft or glans. On microscopic examination the glands contain mucin and are positive for carcinoembryonic antigen. In one reported case, the tumor was metastatic to a single inguinal node. This patient was managed with local excision of the primary tumor and a limited inguinal node dissection and lived 9 years after treatment. Other tumors were managed with local excision and surveillance (Cubilla et al, 1996). In only the seventh reported case (Romero et al, 2006), a patient with a bulky primary mass and inguinal lymph nodes underwent total penectomy and delayed ILND and PLND with a final pathologic stage of pT2N3M0 and was free of disease at 5-year follow-up.

Lymphoreticular Malignant Neoplasm

Primary lymphoreticular malignant neoplasm rarely occurs on the penis (Dehner and Smith, 1970). Leukemia may infiltrate the corpora, resulting in priapism (Pochedly et al, 1974). A thorough search for systemic disease is necessary when lymphomatous infiltration of the penis is diagnosed. If the penile lesion is indeed a primary tumor, systemic chemotherapy may be administered. It is the most effective therapy for local disease, for potential occult deposits that may exist elsewhere, and for preservation of form and function (Marks et al, 1988). Local low-dose radiation therapy has also been reported to be successful (Stewart et al, 1985).

Metastases

Metastatic lesions to the penis are unusual, with fewer than 300 cases reported in the literature (Belville and Cohen, 1992) until the early 1990s. Their infrequency is somewhat puzzling when one considers the rich blood and lymphatic supply to the organ and its proximity to the bladder, prostate, and rectal areas frequently involved with neoplasm. It is from these three organs that the majority of metastatic penile lesions originate (Abeshouse and Abeshouse, 1961). The most likely routes of spread are by direct extension, retrograde venous and lymphatic transport, and arterial embolism. Other sources of penile metastases emanate from the gastrointestinal tract, testis, and kidney (Belville and Cohen, 1992).

The most frequent sign of penile metastasis is priapism; penile swelling, nodularity, and ulceration have also been reported (McCrea and Tobias, 1958; Abeshouse and Abeshouse, 1961; Weitzner, 1971). Urinary obstruction and hematuria may occur. The most common histologic feature of penile invasion by metastatic lesions is the replacement of one or both corpora

cavernosa, which explains the frequent occurrence of priapism. Solitary cutaneous, preputial, and glandular deposits are less common.

The differential diagnosis includes idiopathic priapism; venereal or other infectious ulcerations; tuberculosis; Peyronie plaque; and primary, benign, or malignant tumors.

Penile metastases represent an advanced form of virulent disease and usually appear rather rapidly after recognition and treatment of the primary lesion (Abeshouse and Abeshouse, 1961; Hayes and Young, 1967; Mukamel et al, 1987). On rare occasions a long period may elapse between the treatment of the primary lesion and the appearance of penile metastases (Abeshouse and Abeshouse, 1961) or the penile lesion may occur as the initial and only site of metastasis. In one report of 17 patients with penile metastases, 14 patients died of disseminated disease, with a median survival of 5 months after the diagnosis of penile metastases (Chaux et al, 2011).

Because of the association of a penile metastatic lesion with advanced disease, survival after its presentation is limited, and the majority of patients die within 1 year (Robey and Schellhammer, 1984; Mukamel et al, 1987; Fischer and Patrick, 1999). Successful palliative treatment may occasionally be possible in the case of solitary nodules or localized distal penile involvement if complete excision by partial amputation succeeds in removing the entire area of malignant infiltration (Spaulding and Whitmore, 1978). The prospect for surgical cure is minimal if proximal corporeal invasion is present. Penectomy is occasionally indicated after failure of other modalities to palliate intractable pain (Mukamel et al, 1987). Pain can also be managed by dorsal nerve section (Hill and Khalid, 1988). In general, radiation therapy has been unsuccessful, and chemotherapy has not been employed in a sufficient number of cases to warrant definitive recommendations.

KEY POINTS: NONSQUAMOUS MALIGNANT NEOPLASMS

- Basal cell carcinoma represents a highly curable variant with a relatively low metastatic potential.
- Sarcomas are prone to local recurrence; regional and distant metastases are rare. Superficial lesions can be treated with less radical procedures.
- Melanoma is an aggressive form of cancer but can be cured if diagnosed and treated with the appropriate surgical procedure at an early stage.
- EMPD disseminates by intraepidermal spread initially. Wide local excision to achieve negative margins is the therapy of choice. Invasive EMPD can be lethal.
- Penile metastases most often represent spread from a clinically obvious existing primary tumor. Prognosis is poor, and therapy should be directed toward the primary tumor site histology and local palliation.

Benign Urethral Tumors

Male Urethral Cancer

BENIGN URETHRAL TUMORS

Benign tumors of the urethra are quite rare, with only a few small series and case reports available in the literature. Leiomyoma, hemangioma, and fibroepithelial polyp are most frequently reported.

Leiomyoma

Leiomyomas of the urethra occur primarily in women, most commonly in the third and fourth decade of life. As of 1995, 36 cases had been reported in the English language literature (Leidinger and Das, 1995). Leiomyomas may be urethral or paraurethral in location, and tumor may protrude from the urethral meatus (Lee et al, 1995; Goldman et al, 2007). The most common clinical presentations include palpable anterior vaginal mass, irritative voiding symptoms, urinary tract infection, and hematuria. Obstructive urinary symptoms occur less frequently (Fry et al, 1988; Leidinger and Das, 1995). Leiomyomas also may be discovered incidentally during routine pelvic examination or an unrelated surgical procedure (Cornella et al, 1997). A percentage of these tumors have been reported to be hormonally sensitive based on changes in size during pregnancy and after delivery (Fry et al, 1988; Leidinger and Das, 1995). In many cases, diagnosis is aided by ultrasonography or magnetic resonance imaging (MRI). Paraurethral leiomyoma may be excised via a transvaginal approach, whereas intraurethral lesions are treated with transurethral resection (Cornella et al, 1997). Tumor recurrence is rare, and all reported urethral leiomyomas to date have followed a benign course (Goldman et al, 2007).

Hemangioma

Urethral hemangiomas are more common in males, and the majority of tumors initially described in the literature were located within the anterior urethra (Manuel et al, 1977). Most patients present within the second or third decade of life, although it is not uncommon for symptoms to have been present for years (Roberts and Devine, 1983). Urinary tract hemangiomas may be associated with the presence of cutaneous hemangiomas or congenital disorders such as Klippel-Trenaunay syndrome (Klein and Kaplan, 1975; Jahn and Nissen, 1991). The most common symptom of a urethral hemangioma is intermittent hematuria, which can be massive at times (Parshad et al, 2001). Bloody urethral discharge or hematospermia also may be noted. Diagnosis is made by cystoscopy, but this modality may underestimate the overall extent of the hemangioma (Manuel et al, 1977; Hayashi et al, 1997). MRI may be helpful in select cases to better delineate the extent of the lesion as with other tumors of the penis (Stewart et al, 2010). Smaller hemangiomas are generally treated with transurethral fulguration or laser; however, recurrent bleeding as a result of inadequate ablation may occur. In this setting, or when the hemangioma is more extensive, open excision with one- or two-stage urethral reconstruction may be required for cure (Roberts and Devine, 1983; Parshad et al, 2001).

Female Urethral Cancer

Posterior urethral hemangioma has more recently been recognized as a cause of hematospermia and/or hematuria after ejaculation or erection in older men (Hayashi et al, 1997; Saito, 2008). The lesions typically occur between the verumontanum and the external urethral sphincter. The most common appearance is that of a small sessile lesion with associated varicosities, with pathology demonstrating cavernous hemangioma in most cases. Symptomatic posterior urethral hemangiomas respond well to transurethral resection and fulguration (Saito, 2008).

Fibroepithelial Polyp

Fibroepithelial polyps (FEPs) are benign tumors of mesodermal origin that can occur in the upper or lower urinary tract (Kumar et al, 2008). Urethral FEPs are rare and usually are diagnosed in males during the first decade of life (Aita et al, 2005). The most common clinical presentation in adults is restriction of the urinary stream, frequency, and dysuria (Kumar et al, 2008). Urinary retention is less common but has been reported (Salehi et al, 2009). Diagnosis is made by a combination of cystoscopy, retrograde urethrography, and voiding cystourethrography. FEPs are most commonly located in the posterior urethra in males (Tsuzuki and Epstein, 2005), but have been reported in the bulbar urethra (Kumar et al, 2008). They may arise from the urethra and protrude from the meatus in women (Yamashita et al, 2004; Aita et al, 2005). Transurethral resection is the treatment of choice and is usually curative. Pathologic examination is required to confirm the diagnosis and rule out a more aggressive lesion such as urothelial papilloma or inverted papilloma (Tsuzuki and Epstein, 2005).

MALE URETHRAL CANCER

General Considerations

Carcinoma of the male urethra is rare and usually manifests in the fifth decade of life (Dalbagni et al, 1999). A recent analysis of the National Cancer Institute Surveillance, Epidemiology, and End Results (SEER) database identified 2065 men diagnosed with primary urethral cancer in the United States between 1988 and 2006. Approximately 88% of the patients were white, and 8% African-American (Rabbani, 2011). Etiologic factors include chronic inflammation resulting from a history of frequent sexually transmitted diseases, urethritis, and urethral stricture, and there is likely to be a causal role for human papillomavirus 16 in squamous cell carcinoma of the urethra (Weiner et al, 1992; Cupp et al, 1996). The onset of malignant change in a patient with chronic urethral stricture disease may be insidious, and a high index of clinical suspicion is required to diagnose these tumors expeditiously. More than 50% of patients have a history of urethral stricture disease, almost 25% have a history of sexually transmitted disease, and 96% are symptomatic at presentation (Dalbagni et al, 1999). The most common manifesting symptoms are urethral bleeding, a palpable urethral mass, and obstructive voiding symptoms.

Pathology

Tumors of the male urethra are categorized according to location and histologic features of the cells lining the urethra (Mostofi et al, 1992) (Fig. 38-1). The bulbomembranous urethra is involved most frequently, accounting for 60% of tumors, followed by the penile urethra (30%) and prostatic urethra (10%). Although traditionally it has been held that the majority of primary urethral cancers were squamous cell carcinomas, the SEER study by Rabbani revealed transitional cell carcinoma in 77.6%, squamous cell carcinoma in 11.9%, adenocarcinoma in 5%, and other histologies in 5.5% (Rabbani, 2011). The histologic subtype of urethral cancer varies by anatomic location. Carcinomas of the prostatic urethra are of transitional cell origin in 90% and of squamous cell origin in 10%; carcinomas of the penile urethra are of squamous cell origin in 90% and of transitional cell origin in 10%; and carcinomas of the bulbomembranous urethra are of squamous cell origin in 80%, transitional cell origin in 10%, and adenocarcinoma or undifferentiated in 10% (Grigsby and Herr, 2000).

Urethral carcinoma in males can spread by direct extension to adjacent structures, usually involving the vascular spaces of the corpus spongiosum and the periurethral tissues, or it can metastasize through lymphatic embolization to regional lymph nodes. The lymphatics from the anterior urethra drain into the superficial and deep inguinal lymph nodes and occasionally into the external iliac lymph nodes. Tumors of the posterior urethra most commonly spread to the pelvic lymph nodes. Palpable inguinal lymph nodes occur in approximately 20% of cases and almost always represent metastatic disease, in contrast to penile cancer, in which a large percentage of palpable nodes may be inflammatory. Hematogenous dissemination is uncommon except in advanced disease.

Evaluation and Staging

The tumor, node, metastasis (TNM) staging classification is based on depth of invasion of the primary tumor and presence or absence

of regional lymph node involvement and distant metastasis (Table 38-1). Examination under anesthesia, consisting of cystoscopy and bimanual palpation of the external genitalia, urethra, rectum, and perineum, aids in evaluating the extent of local involvement by tumor. Transurethral or needle biopsy of the lesion is also performed. Cytologic studies of voided urine do not seem to be a reliable method for diagnosis of primary urethral carcinoma. In one study, sensitivity was greatest in men with transitional cell carcinoma (80%) and in those with tumors involving the pendulous urethra (73%) (Touijer and Dalbagni, 2004). If rectal involvement is suspected on bimanual examination or by the patient's symptoms, an evaluation of the lower colon by barium enema study and flexible sigmoidoscopy is recommended to assist with surgical planning. Local soft tissue involvement, lymph node involvement, bone extension, and the presence of distant metastatic disease are best evaluated by a computed tomography (CT) scan of the chest, abdomen, and pelvis or in some cases by MRI. MRI may be particularly helpful for detecting invasion of the corpora cavernosa and is the most sensitive staging modality for the assessment of local tumor extent (Fig. 38-2) (Vapnek et al, 1992; Stewart et al, 2010).

TABLE 38-1 Urethral Cancer Tumor, Node, Metastasis Staging System

PRIMARY TUMOR (T) (MALE AND FEMALE)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	Noninvasive papillary, polypoid, or verrucous carcinoma
Tis	Carcinoma in situ
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades any of the following: corpus spongiosum, prostate, periurethral muscle
T3	Tumor invades any of the following: corpus cavernosum, beyond prostatic capsule, anterior vagina, bladder neck
T4	Tumor invades other adjacent organs
TRANSITIONAL CELL CARCINOMA OF THE PROSTATE	
Tis-pd	Carcinoma in situ, involvement of the prostatic ducts
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades any of the following: prostatic stroma, corpus spongiosum, periurethral muscle
T3	Tumor invades any of the following: corpus cavernosum, beyond prostatic capsule, bladder neck (extraprostatic extension)
T4	Tumor invades other adjacent organs (invasion of the bladder)
REGIONAL LYMPH NODES (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node, 2 cm or less in greatest dimension
N2	Metastasis in a single lymph node, more than 2 cm but less than 5 cm in greatest dimension; or in multiple nodes, none greater than 5 cm
N3	Metastasis in a lymph node greater than 5 cm in greatest dimension
DISTANT METASTASIS (M)	
MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

Figure 38-2. Magnetic resonance image demonstrating large bulbospongiosus urethral cancer (arrow). P, penis; R, rectum.

Treatment

As in penile carcinoma, the primary form of treatment for men with urethral carcinoma is surgical excision. In general, anterior urethral carcinoma is more amenable to surgical control, and the prognosis is better than that of posterior urethral carcinoma, which is often associated with extensive local invasion and distant metastasis (Zeidman et al, 1992). A large series reported overall survival rates of 83% for low-stage tumors, 36% for high-stage tumors, 69% for anterior tumors, and 26% for those in the posterior urethra (Dalbagni et al, 1999). Similarly, a more recent study of 29 patients, 26 of whom underwent initial surgical excision, demonstrated 5-year overall survival rates of 67% for low-stage disease, 33% for high stage, 72% for anterior tumors, and 36% for posterior tumors. The majority of patients received some form of adjuvant radiation therapy or chemotherapy (Thyavichally et al, 2006).

Carcinoma of the Penile Urethra

Transurethral resection, local excision, or distal urethrectomy and perineal urethrostomy may be acceptable treatment in selected patients with superficial, papillary, or low-grade tumors. Long-term disease-free survival has been reported in this setting (Mandler and Pool, 1966; Konnak, 1980; Gheiler et al, 1998; Hakenberg et al, 2001; Karnes et al, 2010). Squamous cell carcinoma in situ of the penile urethra may extend into the distal urethra (Fig. 38-3) and has been successfully treated with partial glansectomy and distal urethrectomy with simultaneous urethral reconstruction (Nash et al, 1996) or penile urethrostomy (Fig. 38-4). In 2007, Smith and colleagues (2007) published results following penile-preserving surgery in 18 patients with squamous cell carcinoma of the penile urethra, 11 of whom had T2 and T3 disease. All underwent surgical excision with reconstruction and penile preservation, with no local recurrences. The authors therefore concluded that this was a feasible approach, and overall survival was not affected by the surgical procedure.

Partial penectomy with a 2-cm negative margin remains the traditional treatment for tumors infiltrating the corpus spongiosum and localized to the distal half of the penis. Excellent local control after this procedure has been documented (Kaplan et al, 1967; Ray et al, 1977; Anderson and McAninch, 1984; Hopkins et al, 1984; Dinney et al, 1994; Gheiler et al, 1998). If invasive

Figure 38-3. Squamous cell carcinoma in situ (erythroplasia of Queyrat) of the glans penis surrounding the urethral meatus. The patient also had significant extension of disease into the distal urethra.

Figure 38-4. Partial glansectomy and distal urethrectomy (same patient as in Figure 38-3). After negative margins were ensured, penile urethrostomy completed the procedure.

disease extends to or involves the proximal penile urethra, total penectomy is required to obtain an adequate margin of excision (Fig. 38-5). A local recurrence rate of 13% has been reported after this procedure (Kaplan et al, 1967). It is important to emphasize that accurate staging is critical to avoid underestimation of the proximal extent of the tumor. Review of previous data would suggest that radical penectomy is an insufficient operation for bulbous urethral tumors (Zeidman et al, 1992).

Although some instances of tumor control by irradiation have been reported, in general, primary radiation therapy has been reserved for patients with early-stage lesions of the anterior urethra

Figure 38-5. Large penile mass in a patient with transitional cell carcinoma of the penile urethra.

who refuse surgery. A commonly used technique consists of parallel opposed fields with the penis suspended vertically by a urethral catheter (Heysek et al, 1985). Radiation therapy has the advantage of potentially preserving the penis, but it may result in skin ulceration or necrosis, urethral stricture, or chronic edema. The long-term results of radiotherapy are difficult to evaluate because few reports are available of male patients treated with this modality (Raghavaiah, 1978; Forman and Lichter, 1992; Koontz and Lee, 2010).

Chemoradiation has been reported as a treatment modality for patients with invasive anterior urethral cancer with the intent of genital preservation (Cohen et al, 2008). The study group included nine patients with disease in the penile urethra who received a defined protocol of mitomycin-C (MMC) and 5-fluorouracil (5-FU) along with concurrent external beam radiation therapy. Five patients demonstrated a durable complete response and required no further therapy except for treatment of urethral stricture. One patient underwent subsequent salvage surgery for local recurrence and remained with no evidence of disease at last follow-up examination. Although the number of patients is limited, this may represent a reasonable consideration for effective tumor treatment with the potential for genital preservation; further study is needed. The outcome of the entire patient cohort is discussed further in the following section.

As opposed to patients with penile cancer, survival benefit from prophylactic inguinal lymph node dissection in patients without palpable inguinal nodes has not been demonstrated with urethral cancer. However, cases of cure with limited nodal disease have been reported and therefore inguinal lymphadenectomy should be considered in the presence of palpable inguinal lymph nodes. This also serves to prevent local problems such as skin breakdown, wound drainage, and vascular erosion.

Carcinoma of the Bulbomembranous Urethra

Early lesions of the bulbomembranous urethra have been treated successfully by transurethral resection or by segmental excision of the involved urethral segment with an end-to-end anastomosis. Unfortunately, cases appropriate for limited resection are rare. Poor survival figures have been recorded for all forms of treatment, but radical excision continues to be an important component of treatment in some patients. Radical cystoprostatectomy, pelvic lymphadenectomy, and total penectomy often are required. Extending the operation to include in-continuity resection of the pubic rami and the adjacent urogenital diaphragm may improve the margin of resection and local control (Mackenzie and Whitmore, 1968; Shuttleworth and Lloyd-Davies, 1969; Bracken, 1982; Klein et al, 1983; Dinney et al, 1994). Limited cases of urethrectomy alone with perineal urethrostomy for infiltrating tumors confined to the corpus spongiosum have been reported (Hakenberg et al,

Figure 38-6. Shaded area outlines the portions of the ischiopubic rami excised at the time of inferior pubectomy during radical excision of bulbomembranous urethral cancer. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2003-2010. All Rights Reserved.)

2001). Total urethrectomy with bladder preservation, bladder neck closure, and creation of a continent catheterizable stoma may be an alternative in select cases (Grivas et al, 2012). The benefit of these more conservative approaches needs to be weighed against the probability of local relapse or dissemination of disease.

Radical extirpation is performed with the patient in the low lithotomy position to allow perineal access. Standard abdominal mobilization of the bladder is completed, except for preservation of the endopelvic fascia and the anterior pubic attachments. A modified λ or inverted U-shaped perineal incision is performed, based just medial to the ischial tuberosities, with the apex in the mid-perineum. The ischiorectal fossae are developed as in perineal prostatectomy, and a tunnel is bluntly dissected just anterior to the rectum, extending from one fossa to the other. The inferior skin flap is mobilized by sharply dividing the intervening subcutaneous tissue and rectourethral muscle. The superior flap is mobilized by sharply incising the subcutaneous tissue to the superficial Colles fascia and then continuing bilaterally to the adductor musculature at the inferior pubic rami. Circumferential incision of the skin and dartos fascia at the penoscrotal junction is performed, and the corporeal bodies are mobilized for a short distance proximally from the superior aspect of the symphysis pubis to allow subsequent inferior pubectomy. Care must be taken not to carry this dissection too far proximally to avoid breaching the anterior aspect of a locally advanced tumor. The penis is passed downward through the perineal incision. Wider exposure may be gained by dividing the scrotum in the midline if necessary. The scrotum usually can be preserved; however, bulky tumors may necessitate sacrifice of portions of the scrotum or perineal skin. In this setting, the testicles may be preserved in thigh pouches.

To complete the pubic arch resection, the adductor musculature is sharply divided bilaterally from the length of the inferior pubic ramus along the medial margin of the obturator foramen. A Gigli saw is passed along the inferior ramus just posterior to the origins of the transverse perineal musculature. An inferiorly beveled transection is made bilaterally to simplify perineal delivery of the specimen. Alternatively, an osteotome may be used for this purpose. The entire symphysis may be resected for bulky urethral lesions involving the presymphyseal tissues. This is accomplished by division of the superior rami at their junction with the symphysis. For most lesions, however, the bulk of the symphysis can be preserved with resection of the subsymphyseal arch. This procedure is preferred, when possible, to preserve stability of the pelvic girdle, and it results in a much smaller pelvic floor defect. A Gigli saw passed through the obturator foramina, or an osteotome is used to incise the symphysis transversely, joining the foramina (Fig. 38-6). The specimen

Figure 38-7. Surgical specimen after radical cystoprostatectomy, urethrectomy, penectomy, and inferior pubectomy for a large bulbomembranous squamous cell carcinoma.

is delivered en bloc (Fig. 38-7). After hemostasis is secure, the omentum is mobilized to cover the bowel. Large pelvic floor defects, such as occurring after total pubectomy, may be managed with a rectus abdominis muscle flap placed as a pelvic sling. Myocutaneous flaps can be fashioned to close large full-thickness perineal defects (Larson and Bracken, 1982).

Because of the relatively poor outcomes after surgery alone for advanced tumors of the posterior urethra, interest in multimodal therapy in this setting is increasing. Previous studies have evaluated the role of neoadjuvant chemotherapy in patients with advanced stage or metastatic disease. A regimen including methotrexate, vinblastine, doxorubicin, and cisplatin (M-VAC) has been noted to have activity against transitional cell carcinoma but was ineffective against other tumor histologic types (Scher et al, 1988). Dinney and colleagues (1994) reported long-term survival in four of eight patients who presented with metastatic urethral carcinoma and were treated with cisplatin-based chemotherapy and surgical excision. On the basis of this experience, their favored regimen consisted of cisplatin, bleomycin, and methotrexate for squamous cell carcinoma and M-VAC for transitional cell carcinoma.

In 2012 the group from MD Anderson conducted a retrospective study of 44 patients with urethral carcinoma to evaluate the role of cisplatin-based chemotherapy (Dayyani et al, 2013). The study included 28 females and 16 males, and all patients but one had T3 or T4 disease. Forty-three percent had N1 and 16% M1 disease. Histologic subtypes were mixed, with the majority being squamous cell carcinoma, adenocarcinoma, and urothelial carcinoma. Thirty-six patients received one of four platinum-based chemotherapy regimens. Five were complete responders (14%), and 72% of patients achieved a complete response or a partial response. The presented results were not stratified as to gender or histology. Surgical consolidation was then performed in 21 patients, and their mean overall survival was 25.6 months. Of the 9 patients, 4 (44%) with lymph node–positive disease at diagnosis were alive, with a minimum follow-up of more than 3 years. Based on this experience, the authors concluded that it is reasonable to consider neoadjuvant chemotherapy for T3b and T4 tumors, as well as high-risk T2 and T3a lesions.

The combination of chemotherapy and radiation therapy has shown some success in a small number of patients with localized and metastatic urethral cancer (Licht et al, 1995; Oberfield et al, 1996). More commonly, these forms of treatment are combined with surgery in a multimodal approach in patients with advanced stage or metastatic disease (Johnson et al, 1989; Gheiler et al, 1998; Grigsby and Herr, 2000). A more recent study reported 18 patients with invasive urethral carcinoma who were treated initially with chemoradiation consisting of MMC and 5-FU and concurrent external beam radiation therapy to the genitalia, perineum, and inguinal and iliac lymph nodes (Cohen et al, 2008). The number of anterior

and posterior cancers was equal, and 33% were N1 or N2. Fifteen patients demonstrated a complete response. Three nonresponders underwent salvage surgery and eventually died of their disease. Of the 15 patients who experienced complete response, 10 remained with no evidence of disease at last follow-up. In the other 5 patients, local recurrence only developed in 4, who underwent salvage surgery, and 2 remained with no evidence of disease. Mean 5-year disease-free survival after chemoradiation and salvage surgery was 72%. It is interesting to note that the previously identified risk factors of tumor grade, T stage, and presence of nodal metastasis were not predictive in this series (Rabbani, 2011). Although instrumentation or surgery for urethral stricture was required in all complete response patients without local disease recurrence, 11 of 18 overall were spared radical surgery after treatment. Although this report is one of the few with a consistent patient population and treatment regimen, further study of this approach is needed to confirm the findings of this single-institution series.

Management of the Urethra after Cystectomy

General Considerations

Contemporary series have demonstrated the incidence of urethral cancer recurrence that follows cystoprostatectomy to range from 2.1% to 11.1% after cutaneous diversion (Freeman et al, 1996; Hassan et al, 2004; Nieder et al, 2004) and 0.5% to 4% after construction of an orthotopic neobladder (Freeman et al, 1996; Hassan et al, 2004; Nieder et al, 2004; Varol et al, 2004). Early studies indicated that transitional cell carcinoma involving the prostatic urethra, particularly with stromal invasion, significantly increased the probability of postoperative urethral recurrence (Hardeman and Soloway, 1990; Freeman et al, 1996). A large number of patients undergoing radical cystectomy with urinary diversion was more recently analyzed, and demonstrated urethral tumor recurrence in 5% and 7% after 5 and 10 years, respectively (Stein et al, 2005). Involvement of the prostate with tumor (either superficial or invasive) and the form of urinary diversion were independent risk factors. Estimated 10-year incidence of urethral recurrence ranged from 4% in patients with no prostatic involvement and orthotopic diversion (lowest risk group) to 24% in those with invasive prostate disease and cutaneous diversion (highest risk group). The low incidence of urethral recurrence after orthotopic bladder replacement has led most surgeons to feel comfortable proceeding with this form of diversion, as long as the findings on frozen-section biopsy of the distal prostatic urethral margin are normal at the time of cystoprostatectomy (Freeman et al, 1996; Hassan et al, 2004; Nieder et al, 2004; Stein et al, 2005). Preoperative transurethral biopsy of the prostate to assess suitability for continent diversion does not correlate with final urethral margin when the preoperative biopsy is positive and has largely been abandoned in favor of intraoperative frozen section (Kassouf et al, 2008).

Approximately 40% of urethral recurrences are diagnosed within 1 year after cystoprostatectomy, with a median time to diagnosis of 18 months (Clark et al, 2004). However, cases of late urethral recurrence have been reported, indicating the need for prolonged surveillance in these patients (Schellhammer and Whitmore, 1976; Freeman et al, 1996). Urethral wash cytology has traditionally been recommended for urethral monitoring after cutaneous diversion and leads to earlier diagnosis of urethral recurrence than when evaluation is delayed until symptoms occur. However, the presumed survival benefit afforded by surveillance with urethral wash cytology over symptomatic presentation has been called into question (Lin et al, 2003). Voided urine cytology is part of standard surveillance in patients who have undergone orthotopic diversion. Patients with positive results for urine or urethral wash cytology or symptoms of urethral bleeding, discharge, or palpable mass are evaluated with cystoscopy and biopsy. Pelvic CT or MRI may be necessary to aid in assessment of the local extent of larger invasive tumors and to assess for metastatic disease. Patients who develop urethral carcinoma in situ after orthotopic diversion may respond to urethral perfusion

with bacillus Calmette-Guérin, but this treatment is ineffective for those with papillary or invasive disease (Varol et al, 2004).

Total Urethrectomy after Cutaneous Diversion

The high or exaggerated lithotomy position provides optimal exposure for total urethrectomy, with the hips and knees gently flexed and the lower limbs abducted in boot-type stirrups. A modified λ or midline perineal incision (Fig. 38-8) is made, and the subcutaneous tissue and bulbospongiosus muscle are then divided in the midline and retracted to expose the corpus spongiosum. The corpus spongiosum is mobilized circumferentially near the level of the mid-bulbous urethra, and traction is applied to facilitate sharp dissection of the urethra distally, thus separating the corpus spongiosum from the adjacent corpora cavernosa. As dissection proceeds distally, the penis becomes inverted, the corpora cavernosa become bowed, and the glans recedes into the phallus. The penis is essentially turned inside out onto the perineum, and the dissection is completed to the base of the glans. To excise the meatus and glandular urethra, the penis is replaced in its anatomic position, and an

incision is made around the meatus and extended on each side down the ventral aspect of the glans. The distal urethra is then freed from its investments within the glans, and the isolated pendulous urethra is delivered onto the perineum. The deep spongiosum of the glans penis is reapproximated with 4-0 polydioxanone sutures in a horizontal mattress fashion; the surface layer is closed with interrupted 4-0 chromic sutures.

Proximal sharp dissection of the urethral bulb is carried out posteriorly and laterally, staying close to the bulb but avoiding entry, if possible, because bothersome bleeding will result. The urethra is detached from the corporeal bodies anteriorly to the level of the departure of the urethra from the bulb, leaving the specimen attached only by the membranous urethra itself. The bulbar arteries are usually identified at the 4-o'clock and 8-o'clock positions just inferior to the perineal membrane after they are transected during the posterior bulb dissection. They are controlled with electrocautery or suture ligation, or they can be ligated if they are identified before transection. **Care must be exercised in completing the proximal dissection, in view of the possible postcystectomy adherence of intestine to the superior surface of the urogenital**

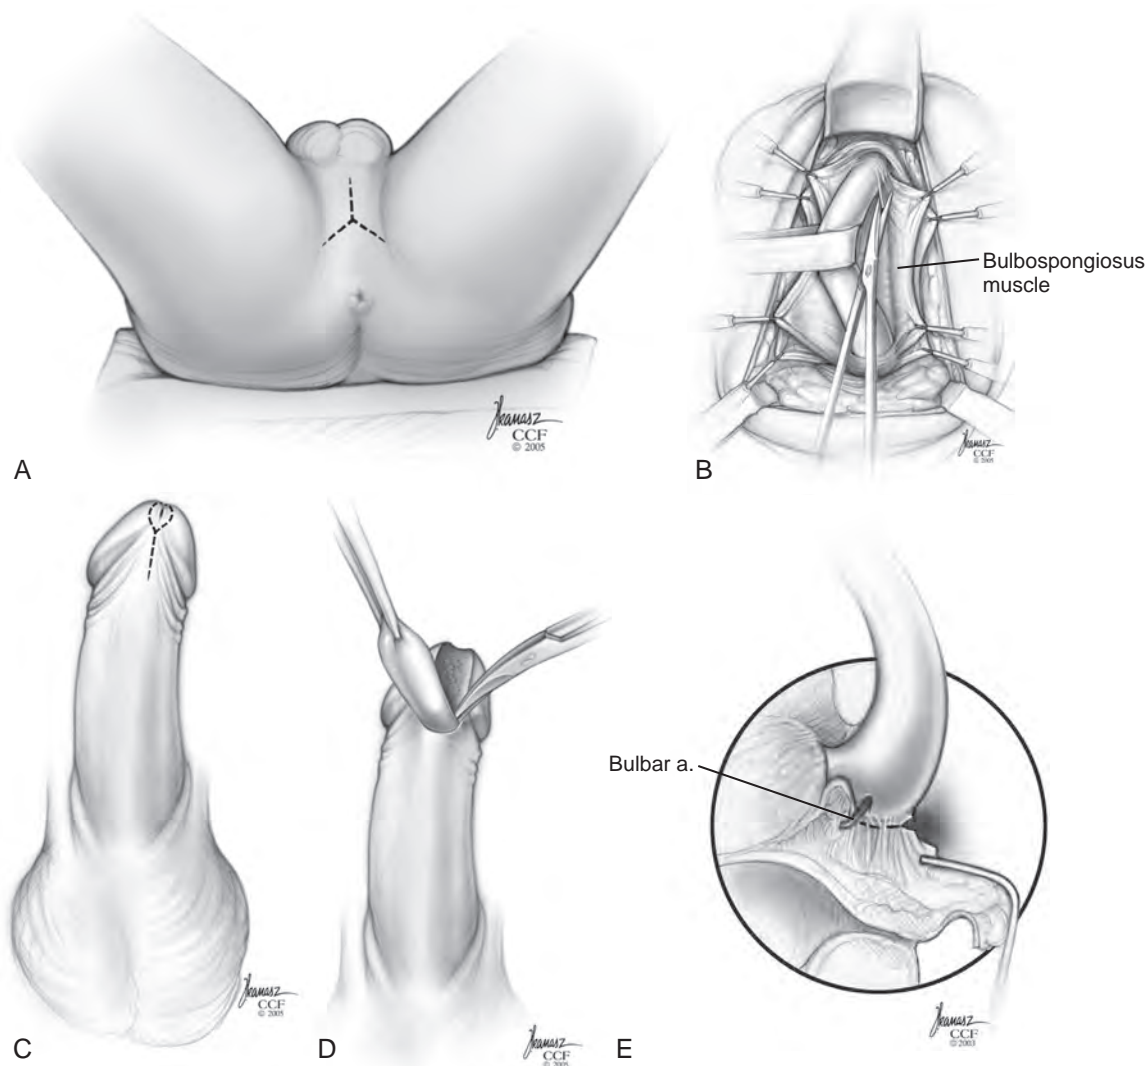

Figure 38-8. Secondary urethrectomy after previous cystoprostatectomy. A, Perineal incision. B, Division of bulbospongiosus muscle to expose the bulb of the corpus spongiosum and initial dissection of the urethra off of the corporeal bodies. C, Distal incision circumscribing the urethral meatus. D, Distal urethral dissection, which then connects to the proximal dissection at the level of the distal shaft. All Rights Reserved.)

diaphragm. This should be done under direct vision, and exposure can be aided by separating the crura of the corporeal bodies in the midline to open the intracural space. All that remains of the membranous urethra proximally is an ill-defined fibrotic band, and it should be completely excised. Frozen-section analysis of this region adds some assurance that a negative proximal margin has been attained. A small suction drain is placed in the urethral bed and brought out through the perineum. Closure of the bulbospongiosus muscle, subcutaneous tissue, and skin with interrupted absorbable sutures completes the procedure, and a light pressure dressing is applied. Superficial hematoma, edema along the penile shaft, and infection are uncommon complications.

Total Urethrectomy after Orthotopic Diversion

Total urethrectomy after orthotopic urinary diversion is performed through an abdominoperineal approach. The patient is placed in lithotomy position with boot-type stirrups that can be adjusted during the procedure. Urethrectomy is carried out to the level of the membranous urethra. Abdominal exploration with lysis of adhesions and mobilization of the orthotopic neobladder is done to the level of the urethral anastomosis. Working with careful palpation from above and below, the area of the membranous urethra and the anastomosis are dissected free in their entirety. A circular area of the pouch adjacent to the anastomosis is excised to ensure an adequate surgical margin, and the specimen is delivered through the perineum. Bleeding from the musculature within the tunnel developed during excision of the membranous urethra can be bothersome and is best controlled with suture ligatures.

In most situations, urinary diversion is accomplished with an ileal conduit. **This often can be carried out with use of bowel from the orthotopic neobladder, which may be reconfigured when necessary, with care taken to incise the bowel along visible lines of previous closure with preservation of the mesenteric blood supply.** The remaining portions of the pouch are excised. If the existing diversion has an afferent limb (e.g., Studer pouch), this segment can be used to construct the conduit without the need for manipulation of the ureters (Bissada et al, 2004). Conversion to a continent cutaneous diversion also may be possible in selected patients, depending on intra-abdominal anatomy and the motivation of the patient (Bartoletti et al, 1999; Taylor et al, 2009).

KEY POINTS: MALE URETHRAL CANCER

- In general, anterior urethral carcinoma is more amenable to surgical control, and the prognosis is better than that of posterior urethral carcinoma, which is often associated with extensive local invasion and distant metastasis.
- As opposed to penile carcinoma, benefit from prophylactic inguinal lymph node dissection has not been demonstrated in urethral cancer.
- Because of the relatively poor outcomes after surgery alone for advanced tumors of the posterior urethra, multimodal therapy should be considered
- The low incidence of urethral recurrence after orthotopic bladder replacement has led most authors to feel comfortable proceeding with this form of diversion, as long as the findings on frozen-section biopsy of the distal prostatic urethral margin are normal at the time of cystoprostatectomy.
- In converting a patient to cutaneous conduit urinary diversion, bowel from the existing orthotopic neobladder often can be reconfigured with its blood supply intact and used for this purpose.

FEMALE URETHRAL CANCER

Epidemiology, Etiology, and Clinical Presentation

A primary malignant neoplasm arising from the female urethra is rare. The literature has reported that despite the female urethra

being much shorter than its male counterpart, primary cancers of the urethra were more common in women than men (Narayan and Konety, 1992). However, more recent study has called this into question. Swartz and colleagues (2006) studied the incidence of primary urethral carcinoma in the United States and found that based on data from the SEER database, between 1973 and 2002, 1615 cases were identified, including 1075 men and 540 women. The ratio of female-to-male predominance had previously been reported as 4:1 (Narayan and Konety, 1992), but based on SEER data there is a 2:1 male-to-female predominance.

Female urethral carcinoma accounts for approximately 0.02% of female cancers (Fagan and Hertig, 1955) and less than 1% of cancers in the female genitourinary tract (Srinivas and Khan, 1987). More than 1200 cases are reported in the literature, most diagnosed in the fifth and sixth decades of life (Srinivas and Khan, 1987). Previously it was noted that approximately 85% of urethral carcinoma cases occur in white women (Terry et al, 1997); however, Swartz and colleagues (2006) reported a greater incidence of primary urethral cancers in African-American women than in white women. They found an overall annual incidence of 1.5 cases per million women, including 4.3 cases per million African-American women and 1.3 per million white women. In the Netherlands, overall crude annual incidence was 0.7 per million women, with peak incidence in the 80- to 84-year-old age group (Derksen et al, 2013).

Incidence appears to increase with age regardless of histologic subtype. The suggestion has been made that the disease is becoming even rarer, because the incidence appears to be decreasing over the time of the SEER study. Although it is likely that misclassification of the site of origin of tumors within the SEER database has led to some inaccuracy in the findings as reported by Swartz, other previous reports are likely biased by the tertiary referral center populations from which these reports originate.

Although the cause of urethral carcinoma in women has not been identified, several factors have been implicated. **Etiologic factors associated with the development of urethral carcinoma include leukoplakia, chronic irritation, caruncles, polyps, parturition, and human papillomavirus infection or other viral infections** (Mevorach et al, 1990; Grigsby and Herr, 2000). Female urethral diverticula also may predispose the patient to malignant change, with perhaps 5% of female urethral carcinomas arising within a diverticulum (Rajan et al, 1993). In a series of 90 women undergoing diverticulectomy, 5 (6%) were found to have invasive adenocarcinoma. Additionally, there was evidence of intestinal metaplasia and dysplasia in some patients (Thomas et al, 2008). Based on immunohistochemical analysis, adenocarcinomas appear to originate from different tissue origins, including (1) Skene glands as a prostatic homologue with resultant prostate-specific antigen positivity in some cases, (2) glandular metaplasia leading to columnar/mucinous adenocarcinoma, and (3) other sources leading to clear cell adenocarcinoma (Dodson et al, 1994; Murphy et al, 1999; Pongtippan et al, 2004; Reis et al, 2011; Papes and Altarac, 2013).

Anatomy and Pathology

Knowledge of urethral anatomy is essential for surgical excision and reconstruction. The female urethra has been divided into an anterior segment (distal third) and a posterior segment (proximal two thirds). **The distal third may be excised while urinary continence is maintained.** The proximal third of the urethra is lined by typical transitional urothelium and the distal two thirds by stratified squamous epithelium (Fig. 38-9). Along its length are submucosal glands composed of columnar epithelium. Lymphatic drainage differs along the course of the female urethra, as in men. Although crossover and communications are possible, lymphatics from the posterior urethra drain to the external and internal iliac and obturator lymph node chains. The anterior urethra and labia drain to the superficial and then to the deep inguinal lymph nodes (Carroll and Dixon, 1992).

The histology of the malignant neoplasm depends primarily on the site of origin within the urethra (see Fig. 38-9). Because of low numbers and varying patient populations, the most predominant

Figure 38-9. Anatomic regions of the female urethra and corresponding histology and histopathology.

cell type varies in different reported series. It is commonly believed that squamous cell carcinoma appears to be the most common histologic type, accounting for 30% to 70% of all cases. Urothelial carcinoma and adenocarcinomas are thought to be the next most common cell types (10% to 25% each). Swartz's review of SEER data found a small majority of cases were urothelial carcinomas and that among women, urothelial carcinoma, squamous cell carcinoma, and adenocarcinoma were noted in 30%, 28%, and 29% of cases, respectively.

A study from Netherlands National Cancer Registry corroborated the SEER data and revealed that even in women, urothelial carcinoma remains the predominant cell type (Derksen et al, 2013). This study of 91 females with primary urethral carcinoma revealed urothelial carcinoma in 45%, squamous cell carcinoma in 19%, and adenocarcinoma in 29% of cases.

Other rarer cell types include lymphoma, neuroendocrine carcinoma, sarcomas, paragangliomas, melanoma, and metastasis (Johnson and O'Connell, 1983; Grabstald et al, 1966; Foens et al, 1991; Forman and Lichter, 1992; Grigsby and Herr, 2000; Swartz et al, 2006). Within urethral diverticula, an increased incidence of adenocarcinomas seems to exist, substantiating the theory that urethral diverticula in some women may arise from a glandular origin, such as the Skene glands (Spencer et al, 1990; Rajan et al, 1993; Gheiler et al, 1998; Thomas et al, 2008; Reis et al, 2011).

Diagnosis and Staging

The evaluation of women with suspected urethral carcinoma includes a thorough pelvic examination, evaluating for a palpable anterior vaginal mass for which the differential should include urethral diverticulum, urethral cancer, urethral polyp, or other benign neoplasm, such as a leiomyoma. Speculum examination should visualize the urethral meatus directly and evaluate for potential involvement of the vaginal wall and vulva. Diagnostic studies include cystourethroscopy and examination under anesthesia. MRI has been used to evaluate pelvic lesions because soft tissue contrast is superior to that with CT and it gives the best anatomic detail in this area. Additionally, MRI can assess local extension and lymph node involvement. Additional staging studies with chest radiograph or chest CT are appropriate. Bone scan may be performed if clinical suspicion exists of bony involvement as a result of bony symptoms or laboratory abnormalities such as elevated alkaline phosphatase or serum calcium. CT with positron emission tomography (CT/PET) may be useful in patients with metastatic disease although its utility is not accurately defined in urethral carcinoma. Serum prostate-specific antigen has been found to be elevated in a small number of case reports of females with adenocarcinoma, and it appears only

a minority of female patients with primary adenocarcinoma of the urethra have this elevated tumor marker (Dodson et al, 1994; Pongtippan et al, 2004). TNM staging for female urethral cancer is identical to that for male urethral cancer (see Table 38-1). Clinically palpable inguinal nodes are found in up to 30% of patients overall, and these are confirmed to be malignant in approximately 90% of cases. Up to 50% of patients with proximal or advanced urethral cancers may have palpable nodes. Pelvic nodal metastases are not uncommon, affecting 20% of cases. Metastasis outside of the pelvis at presentation is rare, however. During follow-up, another 15% of patients will develop metastatic nodal disease (Grigsby and Herr, 2000).

Treatment and Prognosis

Because of the rarity of this tumor and heterogeneity of disease, insufficient experience at any single institution within a reasonable period has precluded attempts to effectively define the natural history of the disease, recommendations for therapy, and follow-up of these patients (Grigsby and Herr, 2000). Although it is conceivable that different histologic subtypes may affect prognosis and the propensity for route of disease spread, most studies have failed to detect any differences in survival based on histologic subtype (Foens et al, 1991; Dimarco et al, 2004). Consequently, lesions of varying histologic type are often treated in a similar fashion. A recent survival analysis of SEER data in 359 women found that squamous cell carcinoma had a longer cancer-specific survival than urothelial or adenocarcinoma histologies (hazard ratio of 2.03 and 1.90, respectively) (Champ et al, 2012).

Treatment recommendations depend primarily on tumor location and clinical stage. Local excision, which should lead to excellent functional results, may be sufficient for the relatively uncommon small, superficial, distal urethral tumors. For more proximal and advanced urethral tumors, a more aggressive approach is warranted. Compared with proximal urethral cancers, distal lesions are associated with improved survival. Five-year disease-specific survival is reported at 71% for distal lesions, 48% for proximal lesions, and 24% for lesions that involve the majority of the urethra (Dalbagni et al, 1998). Surgical and radiotherapy series reflect overall 5-year survival rates of 30% to 40%. Unfortunately, little improvement has been made in treatment of this disease and survival rates have remained statistically unchanged for the last 50 years (Bracken et al, 1976; Prempre et al, 1984; Foens et al, 1991; Dalbagni et al, 1998; Dimarco et al, 2004).

In a study of SEER data encompassing 722 women with primary urethral cancer between 1983 and 2008, 359 women with non-metastatic disease were found to have enough data for cancer survival outcomes to be evaluated (Champ et al, 2012). They found that 5-year and 10-year overall survival was 43% and 32%, respectively. Cancer-specific survival at 5 and 10 years was estimated at 53% and 46%, respectively. Multivariate analysis revealed race (African-American), advanced stage, node-positive disease at time of surgery; nonsquamous histology; and advanced age as being associated with worse cancer-specific survival. Surgery was associated with improved survival, which was not seen for radiation therapy. These data do not indicate that radiation therapy lacks benefit, because selection bias and other confounding factors significantly affect interpretation of this result.

Data from the National Cancer Registry of the Netherlands evaluating 91 females with primary urethral carcinoma reported 46% of patients presenting with advanced disease (stage III or IV). Five-year survival rates of stage 0 to II, stage III, and stage IV were 67%, 53%, and 17%, respectively (Derksen et al, 2013).

Options for treatment of female urethral carcinoma include surgery, radiation therapy, and chemotherapy, alone or in combination. Treatment has trended toward a multimodality approach in recent years based on previously reported outcomes. Use of radiation therapy has increased compared to men treated for urethral carcinoma. In the study of SEER data by Champ and associates (2012), 72% had undergone some cancer-directed surgical procedure and 42% had undergone radiation. Data from the National

Cancer Registry of the Netherlands detailed treatment of 43% of patients with surgery, 16% with radiation, or radiation plus surgery in 22% (Derksen et al, 2013). Although representative of a heterogeneous group of studies, with varying treatment techniques and follow-up, reported results in case series with more than two patients based on primary treatment modalities are summarized in Tables 38-2 and 38-3 for early and advanced disease, respectively.

Distal Female Urethral Carcinoma

Small, exophytic, superficial tumors arising from the urethral meatus or distal third of the urethra may be surgically treated with circumferential excision of the distal urethra and inclusion of a portion of the anterior vaginal wall via a transvaginal approach. Frozen-section specimens of the proximal urethra should be obtained to ensure an adequate margin (Narayan and Konety, 1992). Laser coagulation of small distal tumors has been described (Stahler et al, 1985; Dann et al, 1989). In select patients with T2 or T3 cancer, bladder-sparing strategies also have been employed, if the tumor is more anterior, while an attempt is made to maintain a thorough resection. Dimarco and colleagues (2004) describe radical urethrectomy in the female patient, including excision up to the level of the bladder neck with wide resection of periurethral tissues and anterior vaginal wall. Urinary diversion is then accomplished with a catheterizable stoma (ileovesicostomy or appendicovesicostomy) to the native bladder. Tumors in the distal (anterior) urethra tend to be low stage, and cure rates of 70% to 90% have been achieved with local excision alone. However, in a study by Dimarco and colleagues (2004), 21% of patients with stage T2 or less tumors treated with partial urethrectomy had local recurrence. Other studies of partial urethrectomy, with or without

radiation therapy, for lower stage lesions have recurrence rates of 0% to 50% (Hahn et al, 1991; Gheiler et al, 1998). Meatal stenosis is a common complication, and incidence may be decreased by spatulation of the urethra. Approximation of the anterior vaginal wall and labia may help prevent urinary incontinence, although a sling procedure or other procedure to treat urinary incontinence may need to be subsequently performed. Many authors report minimal complications and rare incontinence from partial urethrectomy, but one series noted de novo or worsening stress urinary incontinence in 42% of patients (Dimarco et al, 2004).

Radiation therapy, as well as surgery, has proved effective for the treatment of low-stage distal urethral carcinomas. An overall 5-year actuarial survival rate of 41% was reported in a series of 84 patients by Garden and colleagues (1993). This was subdivided into 5-year survival of 74% if only part of the urethra was involved and 55% if the entire urethra was involved. Survival appeared to be associated with clinical stage of the tumor (Garden et al, 1993). Radiation may be delivered as external beam, brachytherapy, or combined therapy. In a series of 42 patients treated at the University of Iowa, radiotherapy delivered with combined interstitial and external beam radiation provided fewer local failures (14%) than all radiation-treated patients (36%) or those treated by surgery alone (60%). However, 5-year survival rates for irradiated and surgically treated groups are similar (Foens et al, 1991). Although doses may vary widely, a dose between 55 and 70 Gy is reported in most series. Complication rates, now decreasing, have ranged from 20% to 40%, including urinary incontinence, urethral strictures, necrosis, fistula formation, cystitis, vulvar abscess, and cellulitis (Forman and Lichter, 1992). Radiation may represent an alternative in women when surgical resection would negatively affect functional outcomes. Significant morbidity has been noted with ilioinguinal lymphadenectomy. In addition, female urethral carcinoma often spreads systemically without regional lymph node involvement. Although studies are small, no evidence for improved survival after pelvic or inguinal lymphadenectomy has been found (Grabstald et al, 1966; Levine, 1980; Dimarco et al, 2004). These findings, as well as the inability to prognosticate likelihood for micrometastatic lymph node involvement, led to the recommendation against prophylactic or diagnostic lymphadenectomy. Acknowledging that few objective data exist for making definitive decisions, recommendations for performing groin dissection have been made only for patients who present with positive inguinal or pelvic lymphadenopathy without distant metastasis or patients who develop regional adenopathy during surveillance. Late inguinal lymph node recurrences up to 7 years have been noted. The technique of ilioinguinal lymphadenectomy is identical to the dissection performed in men for penile cancer (Narayan and Konety, 1992; Grigsby and Herr, 2000).

In patients with recurrent or radioresistant tumors, neoadjuvant irradiation followed by local excision resulted in a survival advantage over radiotherapy alone (Grabstald et al, 1966; Peterson et al, 1973; Allen and Nelson, 1978). Despite early and aggressive therapy for anterior lesions, local recurrence rates and mortality remain high. Further studies are necessary to evaluate the potential role of multimodality therapy in these patients.

Proximal Female Urethral Carcinoma

Proximal female urethral carcinomas are more likely to be high stage and may extend into the bladder and vagina. Results with anterior exenteration alone resulted in a 10% to 17% 5-year survival rate and a local recurrence rate of 67% (Bracken et al, 1976; Klein et al, 1983). The poor disease-specific survival and high local recurrence rates observed with single-modality treatment of advanced female urethral carcinoma have led to the recommendation of combination therapy (Dalbagni et al, 1998, 2001; Gheiler et al, 1998). Advanced female urethral carcinoma includes tumors in a proximal location, a lesion that encompasses the entire urethra, or a locally invasive lesion that involves external genitalia, vagina, or bladder. Anterior exenteration (cystourethrectomy), pelvic lymph node dissection, and wide vaginal or complete vaginal excision are often

required to obtain negative surgical margins. If the lesion extends into the external genitalia, partial vulvectomy or labial excision may be necessary. Anterior exenteration is performed as for bladder cancer in a female patient, with a more extensive perineal portion of the procedure to provide wide margins around the urethra. The margins of the lymphadenectomy should include the Cloquet node distally and otherwise retain limits identical to the dissection encouraged for lymphadenectomy in bladder cancer. Anterior exenteration includes the en bloc removal of the entire urethra and bladder, the uterus and adnexa, and the anterior and lateral vaginal walls. On occasion, the entire vagina may need to be resected. The perineal portion is initiated by completing an inverted U-shaped incision to encircle widely around the urethral meatus. It has been suggested that this incision be extended onto the posterior vaginal wall to the labia minora and continued anteriorly to beyond and including the clitoris (Narayan and Konety, 1992). En bloc resection of the pubic symphysis and inferior pubic rami may be necessary if the lesion encroaches anteriorly at the pubis, although the necessity of bone resection has been questioned in ensuring durable local control when intraoperative irradiation is added in suspect cases (Dalbagni et al, 2001).

Radiotherapy alone for proximal invasive urethral carcinoma has yielded poor local control, and 5-year survival rates of 0% to 57% are reported (Grabstald et al, 1966; Johnson and O'Connell, 1983; Prempre et al, 1984; Narayan and Konety, 1992). An improved mean survival rate of 54% at 5 years resulted from the combination of radiation therapy and surgery for high-stage disease (Moinuddin Ali et al, 1988; Terry et al, 1997).

A combination of chemotherapy, radiation therapy, and surgery has been recommended for optimal local and distant disease

control in advanced female urethral cancer. Patients whose treatment fails are thought likely to harbor micrometastatic disease at the time of primary treatment. For patients with squamous cell carcinoma, 5-FU plus MMC has been the most common empirically chosen regimen, in part because of its effectiveness against anal cancers (Kalra et al, 1985). For transitional cell cancers, either M-VAC or a gemcitabine regimen is recommended (Grigsby and Herr, 2000). Chemotherapy given concomitantly with radiation therapy has been shown to interfere with cell repair and thus act as a radiosensitizer. It is hoped that therapy based on this rationale may decrease local recurrence and improve survival by eliminating micrometastatic disease and preventing progression of local failures to systemic failures. The group at Memorial Sloan-Kettering has shown early results based on six patients with advanced proximal urethral tumors treated with a multimodality approach. The authors suggest that anterior exenteration with high-dose intraoperative brachytherapy followed by external beam radiation seems to improve local control. Studies must evaluate whether combined modality therapy proves to decrease distant metastasis and improve survival (Dalbagni et al, 1998, 2001).

For advanced female urethral cancer, we recommend primary chemotherapy and/or radiation therapy for locally advanced tumors. If a radiographic and endoscopic response is realized, consolidative surgery can be considered. Systemic chemotherapy should be considered for metastatic disease.

Urethral Recurrence after Cystectomy in Women

Orthotopic neobladder construction in women is now an established form of urinary diversion after radical cystectomy for

transitional cell carcinoma. The incidence of carcinoma involving the urethra in female patients undergoing cystectomy for bladder cancer ranges from 1% to 13% (Coloby et al, 1994; Stein et al, 1995, 1998; Stenzl et al, 1995). Debate still exists as to whether involvement of the bladder neck is a contraindication to orthotopic diversion; a prospective study revealed that although all patients with urethral transitional cell carcinoma on final pathologic analysis of the cystectomy specimen had involvement of the bladder neck, more than 60% of women with bladder neck involvement had no evidence of urethral transitional cell carcinoma (Stein et al, 1998). Intraoperative frozen-section analysis of the urethral stump has been subsequently espoused by some authors to determine the feasibility of urethra-sparing cystectomy and orthotopic diversion (Stein et al, 1998).

Despite the reported incidence of urethral involvement in patients who have undergone cystectomy and the increased use of orthotopic diversion in women, few cases have been reported of subsequent urethral malignant neoplasms in patients who have undergone this procedure. A review of 1054 patients undergoing radical cystectomy at a single center with a median follow-up of 10 years included 211 women, 44 of whom had an orthotopic urinary diversion. None of the 44 women developed a urethral recurrence (Clark et al, 2004). Subsequently, this group from the University of Southern California reported their first case of primary urethral recurrence in female patients selected for orthotopic urinary diversion. The patient remained without evidence of disease at 4 years of follow-up after total urethrectomy, resection of neobladder neck, and conversion of the orthotopic reservoir to a continent cutaneous urinary diversion (Stein et al, 2008). A report by Taylor and colleagues from MD Anderson (2009) reported on 260 patients after radical cystectomy and orthotopic neobladder, 10 of whom were women. There were six urethral recurrences, all in male patients. In a study by Ali-el-Dein and colleagues (2004), 145 women underwent orthotopic urinary diversion, 61% for squamous cell carcinoma, and 21% for transitional cell carcinoma. At a median follow-up of 56 months, 2 patients (1.4%) developed an isolated urethral recurrence. One patient was reportedly not a surgical candidate, and the other patient underwent urethrectomy and conversion to a continent cutaneous reservoir but died 8 months later (Ali-el-Dein et al, 2004). One additional report described urethral transitional cell carcinoma in a woman after orthotopic diversion. This patient had a high-grade lesion of the bladder base with evidence of nodal metastasis. The patient was treated initially with chemotherapy, followed by urethral resection and conversion to a continent cutaneous diversion. The patient died 5 months later with visceral metastases (Jones et al, 2000). Limited experience to date precludes the ability to make definitive treatment recommendations for women with urethral cancer recurrence after orthotopic diversion. Urethrectomy and surgical resection of the area of the urethra-pouch anastomosis with conversion to a continent cutaneous urinary diversion seem feasible and reasonable in the absence of metastatic disease. Conversion to a cutaneous urinary conduit with use of reconfigured bowel from the existing orthotopic diversion is another option (Bissada et al, 2004).

KEY POINTS: FEMALE URETHRAL CANCER

- The three most common histologies for cancer of the female urethra are urothelial carcinoma, squamous cell carcinoma, and adenocarcinoma—each accounting for approximately 30% of cases.
- Compared with proximal urethral cancers, distal (anterior) lesions are associated with improved survival.
- Tumors in the distal urethra may be low stage, and cure rates of 70% to 90% have been achieved with local excision alone via a transvaginal approach. Radiation may represent an alternative when surgical resection would negatively affect functional outcome.
- Proximal female urethral carcinomas are more likely to be high stage and may extend into the bladder and vagina.
- Optimal treatment for advanced female urethral cancer is not well defined. Multimodal therapy is advocated. A combination of chemotherapy, radiation therapy, and surgery has been recommended for local and distant disease control.
- In appropriately selected women undergoing radical cystectomy and orthotopic diversion for bladder cancer, recurrence of cancer in the retained urethra is a rare event.

Anatomic Considerations

Despite ongoing clinical experience, treatment of squamous cell carcinoma of the penis remains primarily surgical. Early meticulous surgical management with close follow-up typically provides the best opportunity for cure. The most important factor determining survival in patients with penile cancer is the extent of lymph node metastases (Johnson and Lo, 1984; Srinivas et al, 1987; Ravi, 1993; Horenblas and van Tinteren 1994). The management of the inguinal lymph nodes therefore is a major component of the overall treatment strategy, and appropriate decision making with regard to lymph node assessment and excision is critical.

ANATOMIC CONSIDERATIONS

Penile Lymphatics

Squamous cell carcinoma of the penis spreads initially to regional lymph nodes before the occurrence of distant metastatic disease. Lymphatic spread occurs in a systematic fashion along the normal route of penile lymphatic drainage. The superficial lymphatic system consists of vessels draining the prepuce and skin of the penile shaft that converge dorsally and then divide at the base of the penis to drain into the right and left superficial inguinal nodes. The deep lymphatic system consists of drainage from the glans penis toward the frenulum, where large trunks are formed and encircle the corona to unite with those from the other side on the dorsum. They traverse the penis to the base within the Buck fascia, draining through presymphyseal lymphatics into the superficial inguinal nodes and the deep inguinal nodes of the femoral triangle. It is not uncommon for penile cancer to metastasize to the contralateral inguinal nodes because of crossover in the symphyseal region, and this needs to be taken into account in developing a treatment strategy. Drainage subsequently proceeds from the inguinal nodes to the ipsilateral pelvic lymph nodes. It is generally accepted that penile lymphatics drain to the inguinal nodes before proceeding into the iliac nodes (Riveros et al, 1967), although some anecdotal observations have suggested that penile lymphatics may at times drain directly to the external iliac nodes (Lopes et al, 2000). This observation is most likely related to undersampling of the inguinal nodes at the time of lymphadenectomy or at the time of pathologic review. Although penile carcinoma metastatic to the inguinal lymph nodes confers a poorer prognosis overall, aggressive lymphadenectomy is associated with improved long-term survival and potential cure (McDougall et al, 1986; Horenblas and van Tinteren, 1994). In addition, immediate resection of clinically occult lymph node metastases is associated with improved survival when compared with delayed resection of involved nodes at the time of clinical detection (Kroon et al, 2005). If the tumor has spread to the pelvic nodes, long-term survival is less than 10%.

Urethral Lymphatics

Urethral lymphatic drainage runs parallel to the urethra and is located within the mucous membrane and submucosa (Spirin, 1963). This network is most dense in the area of the fossa

Penile Cancer: Surgical Management of Regional Lymph Nodes

navicularis, and these branches join the lymphatics of the glans at the prepuce. The lymphatics of the penile urethra course laterally around the corpora cavernosa to join the vessels proceeding from the glans penis. Bulbar urethral drainage is more variable and may occur along the bulbar artery toward the medial retrofemoral node or may course under the pubis toward the anterior bladder wall, terminating in the retrofemoral and medial external iliac nodes (Wood and Angermeier, 2010).

Inguinal Anatomy

The inguinal lymph nodes are divided into superficial and deep groups, which are anatomically separated by the fascia lata of the thigh. The superficial group is composed of 4 to 25 lymph nodes that are situated in the deep membranous layer of the superficial fascia of the thigh (Camper fascia). The superficial inguinal nodes have been divided into five anatomic groups (Daseler et al, 1948): (1) central nodes around the saphenofemoral junction, (2) superolateral nodes around the superficial circumflex vein, (3) inferolateral nodes around the lateral femoral cutaneous and superficial circumflex veins, (4) superomedial nodes around the superficial external pudendal and superficial epigastric veins, and (5) inferomedial nodes around the greater saphenous vein (Fig. 39-1). The deep inguinal nodes are fewer and lie primarily medial to the femoral vein in the femoral canal. The node of Cloquet is the most cephalad of this deep group and is situated between the femoral vein and the lacunar ligament (Fig. 39-2). The external iliac lymph nodes receive drainage from the deep inguinal, obturator, and hypogastric groups. In turn, drainage progresses to the common iliac and para-aortic nodes.

The blood supply to the skin of the inguinal region derives from branches of the common femoral artery—the superficial external pudendal, superficial circumflex iliac, and superficial epigastric arteries. Complete inguinal dissection necessitates ligation of these branches. Viability of the skin flaps raised during the dissection depends on anastomotic vessels in the superficial fatty layer of the Camper fascia that course lateral to medial along the natural skin lines. Because lymphatic drainage of the penis to the groin runs beneath the Camper fascia, this layer can be preserved and left attached to the overlying skin when the superior and inferior skin flaps are fashioned. On the basis of this anatomy, a transverse skin incision least compromises this blood supply. In this fashion, serious skin slough is prevented in the majority of patients. The femoral nerve lies deep to the iliacus fascia and supplies motor function to the pectineus, quadriceps femoris, and sartorius muscles. In addition, this nerve provides cutaneous sensation to the anterior thigh and should be preserved. Some of the sensory branches, however, are commonly sacrificed in the regional node dissection.

The femoral triangle is bounded by the inguinal ligament superiorly, the sartorius muscle laterally, and the adductor longus medially. The floor of the triangle is composed of the pectineus muscle medially and the iliopsoas laterally. The location of the saphenofemoral junction is estimated to be at a point two fingerbreadths lateral and two fingerbreadths inferior to the pubic tubercle.

PENILE CANCER: SURGICAL MANAGEMENT OF REGIONAL LYMPH NODES

Clinically Negative Groins

Approximately 20% of patients with clinically nonpalpable inguinal nodes harbor occult metastases (Hegarty et al, 2006). Routine bilateral inguinofemoral lymph node dissection (IFLND) in these patients would overtreat 80% of them, subjecting them to potential increased morbidity. The optimal form of management would provide the ability to identify patients with metastatic penile cancer in this cohort who are potentially curable with surgical lymphadenectomy while at the same time avoiding unnecessary surgery in patients with pathologically negative inguinal nodes. Strategies to accomplish this include (1) improved prognostic algorithms and risk assessment based on the primary tumor's pathologic and clinical characteristics, (2) improved radiographic techniques, and (3) pathologic sampling of first-echelon nodes.

The indications for surgical assessment of inguinal lymph nodes when there is no palpable adenopathy are covered in Chapter 37. This section will focus on the techniques used for this purpose. The primary goal of these procedures is to accurately determine whether inguinal nodal metastases are present while minimizing patient morbidity.

Sentinel Node Biopsy

Sentinel lymph node biopsy is the technique to remove nodes that are first affected by the spread of metastatic disease. The theory is that certain cancers typically do not spread to other lymph nodes without the necessary and stepwise involvement of the sentinel node first. Based on anatomic studies, the concept of orderly lymphatic progression of metastatic cells from the primary tumor to the sentinel node does seem to be likely with regard to squamous cell carcinoma of the penis. This approach has gained acceptance as this concept has become more widely accepted, and has also proven effective for both breast cancer and melanoma.

The technique of sentinel node biopsy in patients with invasive squamous cell carcinoma of the penis and clinically negative inguinal regions was proposed by Cabanas (1977) after extensive study of lymphangiograms and anatomic dissections. A 5-cm incision is made parallel to the inguinal crease and centered two fingerbreadths lateral and inferior to the pubic tubercle. By insertion of the finger under the upper flap toward the pubic tubercle, the sentinel lymph node is encountered and excised (Fig. 39-3). Cabanas demonstrated that the sentinel node was always positive in patients with positive metastatic inguinal nodes at time of IFLND. In the absence of tumor in the sentinel node, no metastases were found in the other inguinal lymph nodes in 31 patients. In addition, he reported that this node (subsequently termed the *Cabanas node*) was positive in 4% of patients in whom the lymph nodes were not deemed clinically suspicious. It was concluded that routine excision of this sentinel node could identify patients with micrometastatic disease earlier than waiting for clinically palpable nodes, which was standard at the time.

Although Cabanas reported 90% survival in patients with normal findings on sentinel node biopsy, subsequent authors found the results to be less satisfactory, with false-negative rates of 18% to 25% (Perinetti et al, 1980; Wespes et al, 1986;

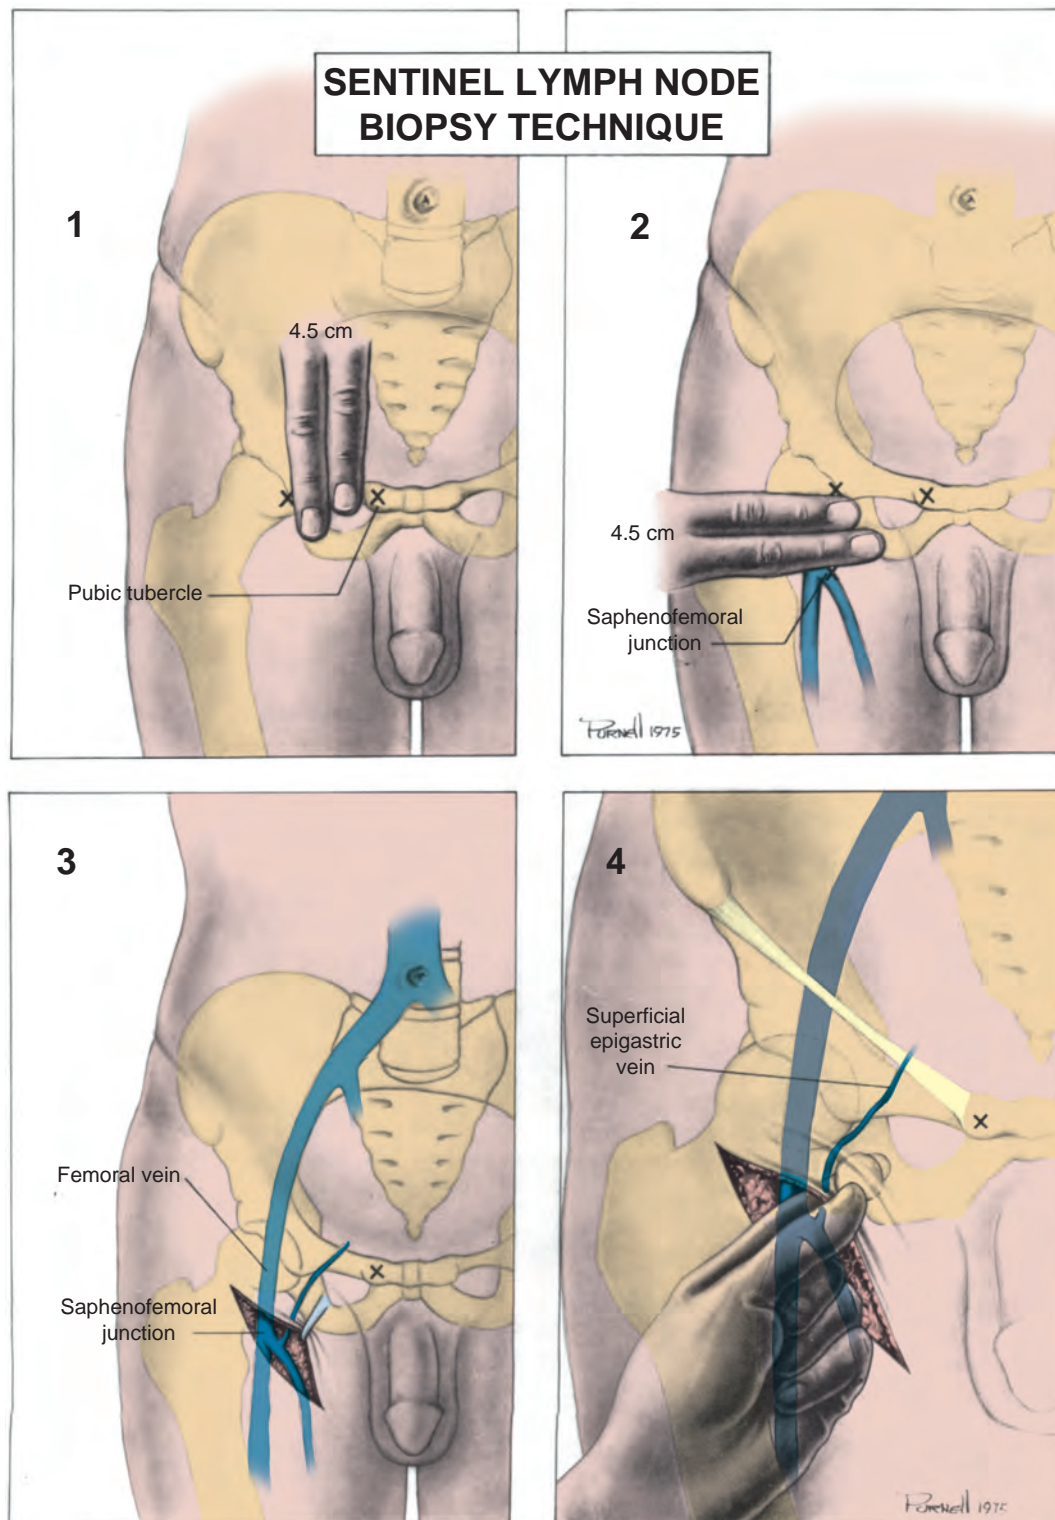

Figure 39-3. Sentinel lymph node biopsy technique as described by Cabanas in 1977. A 5-cm incision is made parallel to the inguinal crease and centered two fingerbreadths lateral and inferior to the pubic tubercle. By insertion of the finger under the upper flap toward the pubic tubercle, the sentinel lymph node is encountered and excised. (From Cabanas RM. An approach for the treatment of penile carcinoma. *Cancer* 1977;39:456–66.)

Srinivas et al, 1991). In large part, this is likely because this initial concept is based on a static location of the sentinel lymph node. As a result, this procedure is no longer recommended. In an attempt to improve sampling of the superficial nodal basin, Pettaway and colleagues (1995) evaluated extended sentinel node

biopsy, during which all of the lymph nodes between the inguinal ligament and the superficial external pudendal vein were removed. This approach has also been abandoned because it resulted in a false-negative rate of 15% to 25% (Ravi, 1993; Pettaway et al, 1995).

Dynamic Sentinel Node Biopsy

Background

Renewed interest in sentinel lymph node biopsy for penile cancer returned as breast and melanoma treatments incorporated this approach successfully. Sentinel lymph node biopsy is now the preferred method of lymph node staging in breast cancer and melanoma (Warycha et al, 2009). The group at the Netherlands Cancer Institute (NKI) pioneered dynamic sentinel lymph node biopsy (DSNB) for staging in penile cancer beginning in 1994. Since then, several groups have reported on the accuracy of DSNB in penile cancer as an alternative or adjunct to IFLND, and this procedure was included in the 2009 European Association of Urology (EAU) guidelines on penile cancer (Pizzocaro et al, 2010). This method includes preoperative lymphoscintigraphy using technetium-99m nanocolloid, preoperative patent blue dye injection, and intraoperative guidance with a gamma ray detection probe to visualize the individual drainage pattern and accurately identify the sentinel node.

DSNB has undergone modifications to reduce false-negative rates. Initial reports out of the NKI revealed a relatively high false-negative rate of 22% (Tanis et al, 2002). Leijte and colleagues reported having found that patients staged by DSNB between 1994 and 2001 had an unsatisfactory false-negative rate of 19%. Further experience and refinement in their technique resulted in a reduction to a reported 5% in patients treated between 2001 and 2004 (Leijte et al, 2007). By combining the data from the NKI in Amsterdam (297 patients) and St. George's Hospital (SGH) in London (134 patients), a false-negative rate of 7% was subsequently achieved (Leijte et al, 2009). They reported a complication rate of 4.7% (28 of 592 explored groins), primarily infection, seroma or lymphocele, or delayed bleeding. A DSNB was classified as a false-negative procedure if a regional nodal recurrence was noted on follow-up after a negative DSNB. Of 323 patients in this study with 611 clinically negative groins, six such recurrences were noted, all within 15 months. The median follow-up for the paper was 17.9 months (range, 1 to 69 months) (Leijte et al, 2009). Subsequent data out of SGH reported on 500 inguinal basins in 264 consecutive men over a 6-year period (2004 to 2010). All patients had T1G2 or higher-stage disease of the primary tumor and nonpalpable nodes in one or both inguinal basins. Minimum follow-up was 21 months (median 57 months). Seventy-three positive inguinal basins (14.6%) in 59 patients (22.3%) were identified. The authors reported a false-negative DSNB rate of 5%. Twenty patients (7.6%) were identified with postoperative complications, half of which were lymphoceles.

Further outcomes of patients treated at NKI were reported based on time period of presentation. Of 1000 patients treated since 1956, 5-year cancer-specific survival increased for each cohort subsequently treated. In patients with cN0 disease, 5-year cancer-specific survival was 91% for patients treated between 1994 and 2012 versus 82% for patients treated between 1956 and 1993. Cancer-specific survival was better in patients treated during the DSNB era than those treated during the prophylactic bilateral IFLND era (Djajadiningrat et al, 2014).

Although the goal of treatment is to find all patients with potentially curable disease, false-negative rates of 5% to 10% are believed by many to be reasonably acceptable given the substantial reduction in morbidity. The ability of other centers to obtain results seen at NKI and SGH and generalize this method has been explored. A retrospective review of DSNB in a tertiary center in Sweden between 1999 and 2011 has been reported (Kirrander et al, 2012). Of 58 patients, 115 cN0 groins were analyzed with DSNB protocol. Two patients with a negative DSNB were noted to have a clinical recurrence, consistent with a false-negative rate of 15%. This study reported an evolving procedure at this institution; for instance, ultrasound was not used preoperatively in 45% of patients in the early time period. Nonetheless, the study confirms that this methodology and technique necessitate dedicated experience to gain optimal results. The false-negative rate of 15% is comparable with

early reports from other series and is expected to fall with increased use and overall experience. In comparison, in the breast cancer literature, recommendations exist that DSNB should be performed by surgeons with at least 20 procedures per year, with the first 20 including assistance from an experienced surgeon. Before routine adoption of the procedure, a false-negative rate below 5% is suggested (Kuehn et al, 2005). The learning curve has not been well established in penile cancer, although in the study of pooled data from NKI and SGH, none of the six recurrences consistent with false negatives occurred in the initial 30 procedures (Leijte et al, 2009). Because of the rarity of penile cancer, these expectations are challenging and provide support for a referral network approach to specialized centers.

Based on the aforementioned information, DSNB should be performed with the goal of a false-negative rate at 5% or lower. Reasons postulated for the false-negative rates seen in penile cancer include (1) selection or identification of the wrong node, (2) poor pathologic sectioning or sampling such that small cancer foci are missed, and (3) tumor occupying and obstructing lymphatic channels that allows for new lymphatics or arborization to occur, leading to unorthodox drainage (Srinivas et al, 1991; Kroon et al, 2004).

Technique

Figure 39-4 outlines the technique and methodology for DSNB as espoused by groups at SGH in London and NKI in Amsterdam (Hadway et al, 2007; Leijte et al, 2007; Lam et al, 2013). Variations in the initial technique have been used to reduce false-negative rates (Kroon et al, 2004). Currently, inguinal ultrasound and fine-needle aspiration (FNA) cytology of suspect lymph nodes has been added as a preliminary step before lymphoscintigraphy. Patients with abnormal nodes on ultrasound undergo FNA, and only patients with negative FNA findings proceed to scintigraphy and DSNB. Patients with positive FNA findings undergo IFLND. The abnormal ultrasound findings used by the group at SGH to direct patients to FNA are outlined in Box 39-1. Ultrasound-guided FNA was added to the DSNB procedure in an attempt to circumvent false-negative results caused by tumor blocking and rerouting of lymphatics. Combined use of a radiotracer and blue dye is then performed to improve the identification of the sentinel node (Fig. 39-5). A meta-analysis performed by Sadeghi and colleagues revealed a pooled detection rate of 88.3%, which was improved to 90.1% if both blue dye and radiotracer were used (Sadeghi et al, 2012). Another change made to the initial DSNB protocol is that an inguinal exploration is performed after removal of the sentinel node. The groin is carefully palpated for suspicious nodes that failed to pick up any radioactive or dye tracer. Finally, a more accurate pathologic analysis of the resected node has also proven essential. A single section through a center of a node may miss micrometastatic disease. All nodes are submitted whole and embedded in paraffin. They are then serially sectioned in 2-mm increments and are evaluated with immunohistochemistry in addition to standard staining to avoid pathologic false negatives.

DSNB can be performed at the time of initial definitive primary tumor resection (after a biopsy of the penile lesion only), or after the primary tumor has been treated (with glans-preserving resection, partial or total penectomy). The group from Amsterdam has reported that postresection DSNB can be done with the technetium-99m nanocolloid injected around the resection wound or scar instead of around the tumor. They found comparable rates of sentinel node visualization (93%), sentinel node identification (100%), and detection of occult metastases (12%) when done after referral following primary tumor resection as when performed synchronously with the penile surgery (Graafland et al, 2010).

Follow-up

Strict follow-up is necessary to identify recurrences that can be managed surgically and potentially salvaged. For patients with a negative ultrasound and negative DSNB, clinical evaluation of the inguinal nodes is recommended. Examination in the office every 3

(Modified from Lam W, Alnajjar HM, La-Touche S, et al. Dynamic sentinel lymph node biopsy in patients with invasive squamous cell carcinoma of the penis: a prospective study of the long-term outcome of 500 inguinal basins assessed at a single institution. *Eur Urol* 2013; 63:657–63; and Leijte JA, Kroon BK, Olmos RA, et al. Reliability and safety of current dynamic sentinel node biopsy for penile carcinoma. *Eur Urol* 2007; 52:170–7.)

months for the first year, every 4 months for the second year, and every 6 months thereafter is recommended. Some patients may have a challenging inguinal nodal examination because of body habitus or lymphedema from prior procedures. In these patients ultrasound can be used. The role of computed tomography (CT), positron emission tomography (PET)-CT, or magnetic resonance imaging (MRI) is not well defined and sensitivity is suboptimal for low-volume metastatic disease. Finally, patients should be instructed on self-examination to be done at regular intervals (i.e., monthly) as an adjunct to their follow-up.

It is important to stress that DSNB remains a diagnostic procedure, allowing some men to avoid a therapeutic IFLND. Those with a positive DSNB should proceed to a full therapeutic lymphadenectomy. It is not appropriate for palpable lymphadenopathy and applies only to clinically negative nodes. In patients with palpable lymphadenopathy, inguinal lymphadenectomy is still recommended, as approximately one half of these patients will harbor pathologically positive lymph node metastases. Finally,

those centers employing DSNB need the experience and dedication of a multidisciplinary team of surgeons, nuclear medicine physicians, radiologists, and pathologists. The occurrence of a false negative is very serious, and salvage is usually difficult. The EAU and the International Consultation on Penile Cancer agree that DSNB is an acceptable staging procedure in the hands of experienced centers. Selection of patients is also dependent on acceptance and commitment of patients for regular follow-ups, as well as self-examination because of the possibility of false-negative findings (Hegarty et al, 2010). Whether the outcomes achieved by experienced centers can be reproduced at other small- or large-volume centers remains to be seen.

Superficial Inguinal Node Dissection

Superficial inguinal node dissection has been proposed as another method to surgically stage penile cancer patients without palpable lymphadenopathy. The procedure consists of removal of the nodal

BOX 39-1 Criteria for Identifying Suspicious Inguinal Lymph Nodes on Ultrasound

Fine-needle aspiration for cytology is performed if one or more of the following are detected:

- Increased size
- Abnormal shape
 - Rounded, with a short-long axis ratio less than 2
 - Eccentric cortical hypertrophy
- Absence of an echogenic hilum
- Hypoechogenicity of the node compared with adjacent muscle
- Lymph node necrosis
- Abnormal vascularity on power Doppler

Figure 39-5. Lymphoscintigraphy: Dynamic images are obtained in multiple projections to provide location of the nodes with radiotracer uptake and their depth. Permanent marker is used to mark the location of each “hot” node. Here, there are two identified right sentinel inguinal lymph nodes and one left sentinel inguinal lymph node.

packet superficial to the fascia lata and centered about the fossa ovalis and saphenofemoral junction. The peripheral boundaries of the dissection are similar to those described later for modified complete inguinal node dissection; however, the fascia lata is not opened. Previous studies have demonstrated no positive nodes deep to the fascia lata unless superficial nodes were also positive (Pompeo et al, 1995; Puras-Baez et al, 1995), which supports the efficacy of this procedure in surgical staging. In addition, a previous study of DSNB included a cohort of patients who underwent complete superficial node dissection. If the superficial nodes were negative, there were no recurrences with follow-up longer than 3 years (Spiess et al, 2007).

Modified Complete Inguinal Lymphadenectomy

In 1988, Catalona proposed a technique of modified inguinofemoral lymphadenectomy designed to provide staging information and therapeutic benefit similar to standard extended lymphadenectomy with less morbidity (Catalona, 1988) (Fig. 39-6). Key aspects of the procedure are (1) shorter skin incision, (2) limitation of the dissection by excluding the area lateral to the femoral artery and caudal to the fossa ovalis, (3) preservation of the saphenous vein, and (4) elimination of the need to transpose the sartorius muscle.

Figure 39-6. Limits of standard and modified groin dissection. (From Colberg JW, Andriole GL, Catalona WJ. Long-term follow-up of men undergoing modified inguinal lymphadenectomy for carcinoma of the penis. *Br J Urol* 1997;79:54–7.)

All of the superficial lymph nodes within the described area are removed, as are the deep inguinal nodes that are located primarily medial to the femoral vein to the level of the inguinal ligament.

The procedure begins by placing the patient into a frog-leg position. A 10-cm skin incision is made approximately 1.5 to 2 cm below the inguinal crease. Skin flaps are developed in the plane just beneath the Scarpa fascia for a distance of 8 cm superiorly and 6 cm inferiorly. The superior dissection is carried to the level of the external oblique fascia with exposure of the spermatic cord. A funiculus of lymphofatty tissue, extending from the base of the penis to the superomedial portion of the lymph node packet, is ligated and divided. Dissection commences in a caudad direction with removal of the superficial and deep inguinal nodes, with the boundaries consisting of the adductor longus muscle medially and the femoral artery laterally. The saphenous vein is identified and preserved, although a number of branches draining into it will need to be sacrificed. The nodal packet is dissected caudad to the level of the skin flap dissection (Fig. 39-7), at which point the lymphatics are carefully ligated and the specimen is delivered from the operative field (Fig. 39-8). A closed-suction drain is placed, and the incision is closed in standard fashion.

The false-negative rate for this procedure, in terms of detecting inguinal metastatic disease, ranges from 0% to 5.5% in the majority of published reports (Parra, 1996; Colberg et al, 1997; Coblenz and Theodoreescu, 2002; Bouchot et al, 2004; d’Ancona et al, 2004).

Morbidity after modified complete inguinal lymphadenectomy consists primarily of minor complications including seroma or lymphocele (0% to 26%), lymphorrhea (9% to 10%), and wound infection or skin necrosis (0% to 15%). These have been self-limited in the majority of patients (Parra, 1996; Coblenz and Theodoreescu, 2002; Jacobellis, 2003; Bouchot et al, 2004; d’Ancona et al, 2004; Spiess et al, 2009). Lower extremity edema has been reported in 0%

to 36% of patients, and persistent clinically significant edema is uncommon.

The primary use of both superficial and modified complete inguinal lymphadenectomy currently is in patients with a primary tumor that places them at increased risk for inguinal metastasis and clinically negative groins on examination (stage T2 or greater, presence of vascular or lymphatic invasion, or high grade). These procedures allow for a more thorough assessment of the superficial inguinal nodal basin, do not require specialized equipment, and are associated with less morbidity than standard inguinal lymphadenectomy. If nodal metastasis is detected on frozen-section examination of the specimen, the procedure is converted to a standard radical IFLND.

Endoscopic and Robotic Inguinal Lymphadenectomy

Background

Endoscopic inguinal lymphadenectomy is a more recent technique with the potential for thorough excision of inguinal nodes with decreased morbidity. Bishoff and colleagues were first to report the use of endoscopic inguinal node dissection, in two cadavers and one patient with penile cancer (Bishoff et al, 2003). The patient required conversion to an open procedure because of inability to adequately mobilize the nodal mass superiorly. In 2006 Tobias-Machado and coworkers reported 10 patients who underwent bilateral lymphadenectomy for nonpalpable inguinal nodes. Standard open lymphadenectomy was performed on one side, and endoscopic on the other. Nodal counts were similar, with 20% complications on the endoscopic side, compared with 70% with open surgery (Tobias-Machado et al, 2006). Sotelo and colleagues reported the outcomes after 14 inguinal endoscopic lymphadenectomies in eight patients with clinical stage T2 squamous cell carcinoma of the penis, with a median operative time of 91 minutes and an average node yield of nine. No wound-related complications occurred (Sotelo et al, 2007). A detailed analysis of immediate and long-term complications using the Clavien classification system in 29 patients undergoing 41 endoscopic inguinal lymphadenectomy procedures revealed minor complications in 27%, and major complications in 14.6% (Master et al, 2012). There were no perioperative deaths. Similar experience has been reported in two recent smaller studies, demonstrating a yield of approximately 7 to 15 lymph nodes per groin and a 20% rate of seroma or lymphocele managed conservatively (Pahwa et al, 2013; Zhou et al, 2013).

In 2009, the first staged bilateral endoscopic operation performed robotically was reported (Josephson et al, 2009). Pathologic examination revealed no metastatic involvement in six superficial and four deep lymph nodes. The contralateral dissection occurred weeks later, and pathologic examination revealed five superficial and four deep negative nodes. There were no wound problems or lower extremity edema. Sotelo and colleagues reported performance of a bilateral procedure without repositioning the robot. Metastatic nodes were present bilaterally, with a yield of 19 lymph nodes on the right and 14 on the left (Sotelo et al, 2013). Matin and colleagues performed a thorough evaluation of the adequacy of a robotic inguinal lymph node dissection by subsequently opening the incision and having a second surgical oncologist look for unretrieved residual nodal tissue in 10 patients. The verifying surgeon's role was to inspect the surgical field to ensure that no additional superficial inguinal lymph nodes (e.g., above the fascia lata of the thigh) remained within the operative field. If additional tissue was removed at that time, it was sent for pathologic analysis to define whether it was nodal in origin and whether it contained metastasis. In one of these groins, two residual lymph nodes were recovered from below the Scarpa fascia along the superficial aspect of the inguinal field near the spermatic cord. No metastases were detected in these additional nodes. Among all patients undergoing robotic dissection, 18 of 19 fields (94.7%) were adequately dissected (Matin et al, 2013).

In summary, there is evidence to suggest that the morbidity of an endoscopic inguinal lymph node dissection is lower than

previously reported for open contemporary series with a similar number of nodes being harvested. The applicability of the robot is a more recent development and will need continued prospective evaluation in comparison with standard laparoscopic endoscopic procedures.

Surgical Technique

The patient is positioned on a split-leg table or in low lithotomy position to allow bilateral groin dissection without repositioning the robot. The assistant stands lateral to the right leg for a right-sided dissection and between the legs for the left side (Figs. 39-9 and 39-10). A Foley catheter is inserted in sterile fashion, after the inguinal and groin areas have been prepared and draped. Bony and soft tissue landmarks are marked on the skin surface, creating an inverted triangle in which the base is a line connecting the anterior superior iliac spine to the pubic tubercle, along the course of the inguinal ligament. The lateral boundary is the sartorius muscle angling toward the apex. The medial boundary is the adductor longus muscle, again extending toward the apex. These marks aid in correct trocar placement as well as in delineating the extent of dissection (Figs. 39-11 and 39-12).

A 2-cm incision is made 3 cm below the inferior aspect of the femoral triangle, approximately 25 cm below the inguinal ligament. A white subcutaneous layer is identified, which corresponds to the Scarpa fascia. Sweeping finger dissection is used to dissect the potential space beneath the Scarpa fascia to develop the skin flaps at the apex of the triangle out in both directions to two additional 8-mm ports (Fig. 39-13). These two primary robotic 8-mm ports are placed with finger-guided techniques laterally and medially. A

subcutaneous workspace is extended with the endoscope by sweeping with the lens itself (Fig. 39-14). The aim of this step is to create a superficial subcutaneous flap under the Scarpa fascia (Fig. 39-15). Alternatively, after the initial finger dissection, a 12-mm Origin balloon port trocar may be used (Origin Medsystems, Menlo Park, CA), set at 25 mm Hg for 10 minutes to create the space (Master et al, 2009). The workspace is then expanded with CO₂ insufflation at a pressure of 15 mm Hg. A 0-degree 10-mm lens is inserted, and one additional intervening 10-mm assistant port is placed between the camera and primary 8-mm working port on the assistant side. The robotic docking is performed as shown in Figures 39-9 and 39-10. The robot is located at 45 degrees contralateral to the first procedure (right side) and lateral to the patient in the second procedure (left side).

Our instrument preference is bipolar Maryland, or PK forceps in the left robotic arm, and monopolar scissors in the right arm to dissect the membranous and lymphatic tissue just deep to the Camper fascia. Every effort is made to completely develop the anterior working space to the inguinal ligament. The inguinal ligament is usually identified at the end of this dissection as being a transverse structure with white fibers, marking the superior limit of the dissection (Fig. 39-16). The boundaries of the dissection extend from the inguinal ligament superiorly, the sartorius muscle laterally, and the adductor longus muscle medially. One will be able to spare the saphenous vein in most patients, and the small branches of the femoral artery and vein may be clipped and divided (see Fig. 39-16). Identification of the adductor longus and sartorius muscles is facilitated by identifying the fascia of the respective muscles and correlating this to the previously made skin markings. The medial spermatic cord is seen medially. Inadvertent dissection

deep to the fascia lata is apparent when reddish muscular fibers are seen.

With blunt dissection, the nodal tissue can be rolled inward on both sides. This maneuver is continued inferiorly as much as possible from both sides to define the inferior apex of the nodal packet. The saphenous vein will be identified as it crosses the internal border of the dissection near the apex of the femoral triangle, and

Figure 39-15. A superficial subcutaneous space is created under Scarpa fascia. FA, femoral artery; FV, femoral vein; N, femoral nerve; SV, saphenous vein.

following the vein leads the surgeon to the saphenous arch until its junction with the superficial femoral vein at the fossa ovalis. The dissection continues superiorly, where the packet is dissected off the fascia lata with a combination of sharp and blunt dissection. Typically the nondominant hand lifts the packet, and the monopolar scissors in the dominant hand advance the dissection. After the fossa ovalis is encountered, the packet is dissected away at its superolateral and superomedial limits, thereby narrowing the packet and pulling it away from the inguinal ligament. At this point the superficial and deep plane of dissection join and separate the package from the inguinal ligament (Fig. 39-17).

With the nodal packet circumferentially dissected except for its attachments to the saphenous arch, venous tributaries are clipped. Characteristic pulsations of the femoral artery serve as a nearby landmark. If possible, the packet will be released from the saphenous vein. If not, the vein can be ligated in the saphenous arch with Weck clips or an endovascular stapler. One must always attempt to preserve the saphenous vein whenever possible, however, to reduce the risk of postoperative lymphedema (Zhang et al, 2007).

The specimen is removed in an Endo Catch bag after extension of the camera trocar incision. Frozen section results determine whether a deep ipsilateral dissection will be required. We typically begin to create the working space in the other leg while waiting for results.

For the deep inguinal node dissection, the pneumoperitoneum is reestablished. The fascia lata medial to the saphenous arch is opened to expose the saphenofemoral junction. Inferomedial dissection around the femoral vein enables resection of the deep inguinal nodes (Master et al, 2009). This should be continued to the level of the femoral canal until the pectineus muscle is seen to ensure complete nodal retrieval (Fig. 39-18).

Insufflation pressure is then decreased to 5 mm Hg to confirm hemostasis. It is of great importance that meticulous control of lymphatics and excellent hemostasis be established to further reduce the risk of formation of lymphocele and/or hematoma, which could potentially become infected. A closed suction drain is positioned in the most dependent (caudal) portion of the lymphadenectomy field such that fluid tends to find the drain when the patient is upright. Trocar incisions are closed in standard fashion. The patient is allowed to ambulate the day of surgery and given a regular diet. Discharge is planned for the first postoperative day. A compressive elastic girdle, used for liposuction patients, is used to provide bilateral compression of the groins. In addition, elastic compression stockings are worn simultaneously and are used for 3

months after surgery (Fig. 39-19). Broad-spectrum antibiotics are continued until after drains have been removed. Drains typically stay in place until the output is less than 50 mL per 24-hour period. All patients receive venous thromboembolism prophylaxis using fractionated or low-molecular-weight heparin.

Palpable Inguinal Adenopathy or Positive Inguinal Nodes

Radical Inguinofemoral Lymph Node Dissection

Radical IFLND is indicated in patients with resectable metastatic adenopathy and may be curative when the disease is limited to the inguinal nodes. We have also favored its use as a palliative procedure in patients with documented inguinal metastasis who are fit for surgery. If left unchecked, cancer-bearing inguinal nodes may lead to significant complications, such as infection or abscess with chronic foul-smelling drainage or life-threatening femoral hemor-

rhage (Fig. 39-20). Antibiotics are often administered preoperatively to reduce the inflammatory component of the regional adenopathy. The patient is positioned with the involved thigh slightly abducted and externally rotated with cushioned support under the flexed knee.

The inguinofemoral dissection is designed to cover an area outlined superiorly by a line drawn from the superior margin of the external ring to the anterior superior iliac spine, laterally by a line drawn from the anterior superior iliac spine extending 20 cm inferiorly, and medially by a line drawn from the pubic tubercle 15 cm down the medial thigh. In most situations the procedure is carried out through an oblique incision approximately 3 cm below and parallel to the inguinal ligament and extending from the lateral to the medial limit of the dissection (Fig. 39-21). If an area of the skin overlying the cancer-bearing nodes is invaded or adherent and requires excision, an elliptical incision is made around the involved skin and then extended medially and laterally. In this setting, the

Figure 39-19. A compressive elastic girdle and elastic compression stockings are placed postoperatively.

incision may alternatively be extended superiorly from the lateral border of the ellipse and inferiorly from the medial border to make a single S-shaped incision for the iliac and inguofemoral dissections (Fig. 39-22).

Superior and inferior skin flaps are developed in the plane just below the Scarpa fascia. The superior flap is elevated cephalad to a point 4 cm above the inguinal ligament, and the inferior flap to the limit of the dissection. The fat and areolar tissues are dissected from the external oblique aponeurosis and the spermatic cord to the inferior border of the inguinal ligament, forming the superior boundary of the lymph node packet (Fig. 39-23). The inferior angle of the inguofemoral exposure is at the apex of the femoral triangle, where the long saphenous vein is identified and divided. In patients with minimal metastatic disease, it may be feasible and beneficial to spare the saphenous vein, and this should be considered (Fig. 39-24). Dissection is deepened through the fascia lata overlying the sartorius muscle laterally and the thinner fascia covering the adductor longus muscle medially. At the apex of the femoral triangle, the femoral artery and vein are identified, and dissection is continued superiorly along the femoral vessels. Superficial cutaneous perforating arteries are ligated as they are encountered on the

Figure 39-22. A, Incision and area of dissection for left inguinofemoral lymph node dissection with excision of adherent skin overlying nodal mass. B, Single-incision approach and area of dissection for right ilioinguinal lymph node dissection with excision of overlying skin.

surface of the femoral artery. The saphenous vein is divided at the saphenofemoral junction, and the dissection is continued superiorly to include the deep inguinal nodes medial and lateral to the femoral vein until continuity with the pelvic dissection is attained at the femoral canal (Fig. 39-25). The anterior aspects of the femoral vessels are dissected, but the femoral vessels are not skeletonized, and the lateral surface of the femoral artery is not exposed. This avoids injury to the femoral nerve and the profunda femoris artery, and the femoral nerve is usually not visible as it runs beneath the iliacus fascia.

After the femoral triangle is dissected (Fig. 39-26), the sartorius muscle is mobilized from its origin at the anterior superior iliac spine and either transposed or rolled 180 degrees medially to cover the femoral vessels. The muscle is sutured to the inguinal ligament superiorly, and its margins are sutured to the muscles of the thigh immediately adjacent to the femoral vessels (Fig. 39-27). The femoral canal is closed, if necessary, by suturing the shelving edge of the Poupart ligament to the Cooper ligament, being careful not to compromise the lumen of the external iliac vein or to injure the inferior epigastric vessels in the process. Primary closure of the inguinofemoral dissection is usually possible with minimal or no further mobilization of the excision margins. When circumstances demand a large area of inguinal soft tissue sacrifice, primary closure may be obtained by scrotal skin rotation flaps (Skinner, 1974), an abdominal wall advancement flap (Tabatabaei and McDougal,

Figure 39-23. Initial dissection for radical inguinofemoral lymph node dissection with exposure of superior border defined by the external oblique fascia. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2003-2010. All rights reserved.)

2003), or a myocutaneous flap based on the rectus abdominis or tensor fasciae latae (Airhart et al, 1982) for more extensive defects.

Closed-suction drains are placed under the subcutaneous tissue and brought out inferiorly. During closure, the skin flaps are sutured to the surface of the exposed musculature to decrease dead space. The skin is closed with absorbable subcutaneous sutures and staples. The patient is maintained on bed rest for 2 or 3 days, and pneumatic compression stockings are used. The drains are removed after 5 to 7 days, when drainage is less than 30 to 40 mL/day. Compression stockings are recommended postoperatively. We maintain the patient on a suppressive dose of a cephalosporin for 1 to 2 months until healed to decrease the incidence of erythema and cellulitis, and this seems to improve overall wound healing.

In the past, complications related to radical ilioinguinal lymphadenectomy have been significant. In contemporary series, early minor complications have been reported in 40% to 56% of dissections (Bevan-Thomas et al, 2002; Bouchot et al, 2004; Nelson et al, 2004; Spiess et al, 2009). These consist primarily of lymphocele, wound infection or necrosis, and lymphedema. Major complications, such as debilitating lymphedema, flap necrosis, and lymphocele requiring intervention, occur in 5% to 21% of patients (Bevan-Thomas et al, 2002; Nelson et al, 2004). Deep venous thrombosis (DVT) or pulmonary embolism (PE) has been reported in 4% to 7% of patients (Johnson and Lo, 1984; Ravi, 1993; Spiess et al, 2009). Efforts to minimize lower extremity lymphedema include early use of compression stockings and saphenous vein preservation when feasible. With regard to DVT and PE, sequential

lower extremity compression devices are placed before surgery. Use of prophylactic fractionated subcutaneous heparin or low-molecular-weight heparin is recommended while the patient is on bed rest, and the current trend is toward earlier ambulation when appropriate (Spiess et al, 2009).

KEY POINTS

- The most important factor determining survival in patients with penile cancer is the extent of lymph node metastases.
- Approximately 20% of patients with clinically nonpalpable inguinal nodes harbor occult metastases.
- Immediate resection of clinically occult lymph node metastases is associated with improved survival when compared with delayed resection of involved nodes at the time of clinical detection.
- In experienced hands, DSNB is an effective minimally invasive technique for assessment of clinically negative groins and should be performed with the goal of a false-negative rate of 5% or less.
- Superficial and modified complete inguinal lymph node dissections allow for a thorough assessment of the superficial inguinal nodal basin, do not require specialized equipment, and are associated with less morbidity than radical inguinal lymphadenectomy.
- There is early evidence to suggest that the morbidity of an endoscopic inguinal lymph node dissection may be lower than previously reported for open contemporary series with a similar number of nodes being harvested.
- Radical IFLND is indicated in patients with resectable metastatic adenopathy and may be curative when the disease is limited to the inguinal nodes.
- Penile cancer metastases to the pelvic lymph nodes do not occur in the setting of negative ipsilateral inguinal nodes.

Principles of Reconstructive Surgery

Selected Processes

Trauma to the Genitalia

Urethral Stricture Disease

Pelvic Fracture Urethral Injuries

Vesicourethral Distraction Defects

Complex Fistulae of the Posterior Urethra

Curvatures of the Penis

Total Penile Reconstruction

Female-to-Male Transsexualism

Improvements in microsurgery, tissue transfer techniques, and tissue handling have expanded the repertoire of the urologic surgeon and the genitourinary reconstructive surgeon in particular. Urologists are now able to reconstruct congenital and acquired genitourinary abnormalities with greater facility. Microvascular and microneurosurgical techniques have made it possible to construct a phallus that allows a patient to void while standing and to enjoy erotic sensibility. Because the phallus has erotic sensibility and protective sensation, the patient can eventually have a prosthetic implantation that allows an acceptable sexual life. This chapter discusses the general principles of male genital reconstructive surgery; specifics include male urethral surgery, surgery for congenital and traumatic penile lesions, and complex fistula and obliterative issues associated with the posterior urethra.

PRINCIPLES OF RECONSTRUCTIVE SURGERY

Many techniques in reconstructive surgery require the transfer of tissue. Skin is one of those tissues, and its properties vary from individual to individual and from place to place on the same individual. Variable characteristics such as color, texture, thickness, extensibility, innate skin tension, and blood supply can be useful in various situations.

The term *tissue transfer* implies the movement of tissue for purposes of reconstruction. In contrast to extirpative surgery, the transfer of tissue for reconstruction requires an intimate knowledge of the anatomy of the donor and the recipient sites as well as of the principles that allow the tissue to survive after it is transferred.

The skin can be used as a model. The superficial layer of the skin is termed the *epidermis* (thickness, 0.8 to 1 mm). The deep layer of the skin is termed the *dermis*. The dermis has two layers: a superficial layer, the *adventitial dermis* (also called the *papillary* or *periadnexal dermis*, depending on the anatomy), and a deep layer, the *reticular dermis*. For genitourinary reconstruction, skin without adnexal structures is often used; the *papillary dermis* is synonymous with the *adventitial dermis*. Other tissues commonly transferred for genitourinary reconstruction include bladder and oral mucosa. The bladder epithelium is the superficial layer of the bladder; the deep layer of the bladder is termed the *lamina propria*, with superficial and deep layers. The oral mucosa is the superficial layer of much of the oral cavity, which also has a deeper layer termed the *lamina propria*, again with superficial and deep layers.

All tissue has physical characteristics: extensibility, inherent tension, and the viscoelastic properties of stress relaxation and creep. The physical characteristics of a transferred unit are primarily a function of the helical arrangement of collagen along with the elastin cross-linkages. The collagen-elastin structure is suspended in a mucopolysaccharide matrix that influences the viscoelastic properties.

Tissue can be transferred as a graft (Fig. 40-1). The term *graft* implies that tissue has been excised and transferred to a graft host bed, where a new blood supply develops by a process termed *take*. Take requires approximately 96 hours and occurs in two phases. The initial phase, *imbibition*, requires about 48 hours. During that phase, the graft survives by “drinking” nutrients from the adjacent graft host bed, and the temperature of the graft is less than the core body temperature. The second phase, *inosculation*, also requires about 48 hours and is the phase in which true microcirculation is reestablished in the graft. During that phase, the temperature of the graft increases to core body temperature. The process of take is influenced by the nature of the grafted tissue and the conditions of the graft host bed. Processes that interfere with the vascularity of the graft host bed interfere with graft take.

The *epidermal*, or *epithelial layer*, is a covering, the barrier to the “outside,” and is adjacent to the superficial dermis, or superficial lamina. At approximately this interface is the superficial plexus. In the case of skin, the plexus is the *intradermal plexus*. There are some lymphatics in the superficial dermal or tunica layer. On the under-surface of the deep dermal layer or deep lamina is the *deep plexus*. In the case of skin, this is the *subdermal plexus*. The deep dermis contains most of the lymphatics and greater collagen content than found in the superficial dermal layer. The deep or reticular dermis is generally thought to account for the physical characteristics of the tissue.

If a graft is a *split-thickness unit*, it carries the epidermis or the covering. The graft also exposes the superficial dermal (intra-dermal or intralaminar) plexus. In most grafts, the superficial plexus comprises small but numerous vessels, which conveys favorable vascular characteristics to a split-thickness unit. The unit has few lymphatics, and the physical characteristics are not carried, which accounts for the tendency of split-thickness units to be brittle and less durable. The reticular dermis is not carried with the split-thickness unit (Jordan, 1993).

A mesh graft is usually an application of the split-thickness graft. After the harvest of a sheet graft, the sheet is placed on a carrier that cuts systematically placed slits in the graft. These slits can expand the graft by various ratios (i.e., 1.5:1, 2:1, 3:1). For

Figure 40-1. Cross-sectional diagrams (histologic appearance above, microvasculature below) of the skin. **A,** Cross-sectional diagrams of skin. **B,** Cross-sectional diagrams of oral mucosa. FTSG, full-thickness skin graft; STSG, split-thickness skin graft. (From Jordan GH, Schlossberg SM. Using tissue transfer for urethral reconstruction. *Contemp Urol* 1993;13:23.)

most genital reconstructive surgery, the slits are not for expansion but rather to allow subgraft collections to escape; in some cases, the slits allow the graft to conform better to irregular graft host beds (e.g., the testes in split-thickness skin graft scrotal construction). It has also been proposed that mesh grafts take readily because of increased levels of growth factors, possibly as a function of the slits. In general, full-thickness skin grafts are not meshed (Schreiter and Koncz, 1983; Jordan, 1993).

If a graft is a full-thickness unit, it carries the covering and the superficial dermis or lamina with all the characteristics attributable to that layer. However, it also carries the deep dermis or deep lamina. In skin, the subdermal plexus is exposed. In most cases, the plexus is composed of larger vessels that are more sparsely distributed. The graft is fastidious in its vascular characteristics. A full-thickness unit carries most of the lymphatics, and the physical characteristics are likewise carried with the transferred tissue (Devine et al, 1976; Jordan, 1993; Wessels and McAninch, 1996). Comparing the grafts that are most commonly used in genitourinary reconstructive surgery, the split-thickness skin graft has favorable vascular characteristics but tends to contract and be brittle when mature. The full-thickness skin graft tends to have more fastidious vascular characteristics, but it does not contract as much and is more durable when mature (see Fig. 40-1A). There is a difference between genital full-thickness skin (penile and preputial skin grafts) and extragenital full-thickness skin. This is probably a reflection of the increased mass of the graft in extragenital skin grafts. This increased mass makes the graft more fastidious, and the poor results reported with urethral reconstruction with extragenital full-thickness skin grafts are probably due to poor or ischemic take (Webster et al, 1984; Webster, 1987; Jordan, 1993). The posterior auricular graft (Wolfe graft) is an exception to the rule concerning extragenital skin. The postauricular skin is thin and

overlies the temporalis fascia and is thought to be carried on numerous perforators. The subdermal plexus of this graft mimics the characteristics of the intradermal plexus, and the total mass of the graft is more like that of the split-thickness unit. In the bladder epithelial graft, there is a superficial and a deep plexus; however, the plexuses are connected by many more perforators. Bladder epithelial grafts tend to have more favorable vascular characteristics. In the case of oral mucosal grafts, there is a panlamellar plexus. The oral mucosal graft can be thinned, provided that a sufficient amount of deep lamina is carried to preserve the physical characteristics (see Fig. 40-1B). Oral mucosal grafts are thought to have optimal vascular characteristics (Humby, 1941; Memmelaar, 1947). The thinned graft diminishes the total graft mass, while preserving the physical characteristics and not adversely affecting the vascular characteristics. The enthusiasm for the buccal mucosal graft seems well founded. The fact that the graft has a "wet epithelial" surface is likewise thought to be a favorable characteristic for many cases of urethral reconstructive surgery. The lingual, labial, and buccal grafts all vary in thickness and in substance. Because the labial mucosal grafts are thin, many surgeons prefer that donor site for reconstruction of the fossa navicularis (Jordan, 1993).

A series by Fichtner and colleagues (2004) reporting the use of "buccal mucosal" onlay grafts with mid-term and long-term results seems to suggest durability for these grafts. In that series, 67 patients were described, all with follow-up exceeding 5 years and some with 10 years of follow-up. All failures occurred within 12 months of the original procedure. More recent studies showed equal results with buccal and lingual grafts (Sharma et al, 2013). The dermal graft has been used for years to augment the tunica albuginea of the corpora cavernosa. When it is harvested, the graft exposes the intradermal plexus and the deep dermal plexus. The dermal

graft takes readily (is not fastidious) and has the physical characteristics normal to skin. When it is properly prepared, the tunica vaginalis graft is essentially peritoneum. The tendency of peritoneum to take readily is well documented in the literature that examines adhesion formation and in the urology literature concerning the application of peritoneal grafts for reconstruction of the urinary tract. The literature fails to define accurately what the surgeon can expect regarding physical characteristics (Jordan, 1993). Tunica vaginalis grafts have proved useful for small defects of the tunica albuginea of the corpora cavernosa, but aneurysmal dilation tends to develop when they are used for larger defects. Tunica vaginalis grafts have been tried for urethral reconstruction with uniformly poor results.

As described in the urologic literature, vein grafts are perhaps not true grafts according to the terminology used in this chapter. Vein patches are widely used in vascular surgery. The premise is that the vein survives by endothelial direct perfusion and reestablishment of vein wall blood flow by perfusion of the vasa vasorum. The vascular literature is at odds with this concept. The intima is the endothelial layer; it is thin and easily injured during the process of vein harvest and preparation, with areas of endothelial sloughing noted. Inflammatory cells and fibrin adhere to the exposed basement membrane. However, the endothelium regenerates in the first 6 weeks. The media is a combination of smooth muscle and interlaced collagen. After graft harvest, smooth muscle injury is prominently noted and is thought to be related to warm ischemia. In more mature grafts, much of the smooth muscle is replaced by a process of fibrous transformation with collagen deposition. The adventitia is a loose collagenous network interspersed with vasa vasorum. Mature vein grafts show evidence of take to the vasa vasorum. However, the adventitia becomes incorporated by periaxial connective tissues. Thrombosis in the vasa vasorum, early in the process of take, is not an unusual phenomenon. When vein grafts are exposed to arterial pressure and shear stress forces, the process colloquially described as "arterialization" occurs and is associated with changes of the vessel wall elastic properties, and the graft becomes rigid with low compliance. When these changes are noted, at least when veins are used for vessel replacement, the graft remains noncompliant throughout the remaining life of the graft (Szilagyi et al, 1973; Fuchs et al, 1978; Tolhurst and Haeseker, 1982). At the present time, vein "grafts" are being widely used for replacement of defects of the tunica albuginea of the corpora cavernosa. The pertinent points with regard to the transfer of vein patches to the corpora cavernosa and their long-term behavior have been inferred from the current vascular literature. Dermal grafts have been tried for urethral reconstruction, also with generally poor results. Rectal mucosal grafts also have been proposed for urethral reconstruction, but little is known about their graft take. In general, the vascularity of the bowel mucosa is based on the vascularity of the underlying muscle, with the mucosa carried on perforators. Little is found in the literature regarding the process of take of these grafts.

Tissue can be transferred as a flap. The term *flap* implies that the tissue is excised and transferred with the blood supply either preserved or surgically reestablished at the recipient site. Flaps can be classified by numerous criteria. Flaps can be classified on the basis of their vascularity and characterized as either random flaps (Fig. 40-2) or axial flaps (Fig. 40-3). A *random flap* is a flap without a defined cuticular vascular territory. The flap is carried on the dermal or laminar plexuses; the dimensions of random flaps can vary widely from individual to individual and from body site to body site. The term *axial flap* means that there is a defined vessel in the base of the flap. There are three types of axial flaps. The *direct cuticular axial flap* is a flap based on a vessel superficial to the superficial layer of the deep body wall fascia (see Fig. 40-3A). The classic example of a direct cuticular flap is the groin flap. A *musculocutaneous flap* (Fig. 40-4A) is based on the vascularity to the muscle. The *overlying skin paddle* is carried on perforators. If the muscle alone is carried as a flap, the overlying skin survives as a random unit. The *fasciocutaneous system* of vascularity (Fig. 40-4B) is similar to the musculocutaneous system.

Figure 40-2. Random flap. The arterial perforators have been interrupted, and flap survival depends on the intradermal and subdermal plexuses.

Figure 40-3. Axial flaps. Large vessels enter the base of the flaps. Survival depends on these vessels and on the random distal vascularity. A, Peninsula flap. The vascular continuity and the cutaneous continuity in the flap base are intact. B, Island flap. The vascular pedicle is intact; the cuticular continuity has been divided. These axial vessels are unsupported (dangling). C, Microvascular free-transfer flap. The free-flap cuticular and vascular connections are interrupted at the base of the flap. Vascular continuity is reconstituted in the recipient area by a microsurgical anastomosis. (From Jordan GH, McCraw JB. Tissue transfer techniques for genitourinary reconstructive surgery. AUA Update Series 1988;7:lesson 10.)

However, the deep blood supply is carried on the fascia (deep and superficial layers), and the overlying skin paddle is based again on perforators. One can transfer a fascial flap based on the deep blood supply associated with the flap; the overlying skin, if it is not carried with the flap, remains as a random unit (Ponten, 1981; Tolhurst and Haeseker, 1982; Cormack and Lamberty, 1984). It has been argued that fascia is relatively avascular and cannot serve as the "blood supply" to the fasciocutaneous unit. Actually, the fascial layer acts as a trellis—the vessels are carried much like the limbs of a vine (Jordan, 1993).

Figure 40-4. A, Musculocutaneous flap. Musculocutaneous perforators from the artery to a muscle vascularize the skin and overlying subcutaneous fat. They may be transferred as free flaps but are usually transferred locally, left attached to the vascular pedicle. B, Fasciocutaneous flap. Perforating blood vessels from rich plexuses on the superficial and deep aspects of the fascia connect to perforator vessels that communicate with the microvasculature of the overlying paddle. In genital reconstruction, these flaps are based on the dartos fascia of the penis or are free flaps from the forearm. (From Jordan GH, McCraw JB. Tissue transfer techniques for genitourinary reconstructive surgery. AUA Update Series 1988;7:lesson 10.)

A flap also can be classified by the elevation technique. A peninsular flap is a flap in which the vascular continuity and the cutaneous continuity of the flap base are left intact (see Figs. 40-2 and 40-3A). An island flap (see Fig. 40-3B) is a flap in which the vascular continuity is maintained; however, the cuticular continuity is divided. A true island flap is elevated on dangling vessels. The microvascular free-transfer flap (free flap) (see Fig. 40-3C) has the vascular continuity and the cuticular continuity interrupted. The vascular continuity is then reestablished at the recipient site.

The terminology is confusing. In genitourinary reconstructive surgical procedures, we tend to use the term *island flap*. As already mentioned, a true island flap is elevated on dangling vessels. However, the usual case is that a skin island or paddle is elevated either on the muscle, as in the gracilis musculocutaneous flap, or on the fascia, as in local genital skin flaps. The term *island flap* is not synonymous with the terms *skin island* and *skin paddle*. The usefulness of these flaps and grafts is illustrated in the discussion of surgical techniques later in this chapter. There is continued interest in the use of tissue-cultured grafts or “manufactured” grafts. The likelihood of someday being able to use off-the-shelf grafts or sheets of cultured material successfully is not far in the future (Chen et al, 1999; Atala, 2002; Rotariu et al, 2002; El-Kassaby et al, 2003; Bhargava et al, 2004).

Anatomy of the Penis and Male Perineum

Please see the Expert Consult website for this section, including Figures 40-5 to 40-13.

KEY POINTS: PRINCIPLES OF RECONSTRUCTIVE SURGERY

- Many of the techniques in reconstructive surgery require the transfer of tissue. Tissue transfer implies the movement of tissue for purposes of reconstruction. All tissue has extensibility, inherent tension, and the viscoelastic properties of stress relaxation and creep. These physical characteristics are important in predicting the behavior of transferred tissue.
- A graft is tissue that has been excised and transferred to a graft host bed, where a new blood supply develops by a process termed *take*. A flap is tissue that has been excised and transferred with the blood supply preserved or surgically reestablished at the recipient site. Grafts that have been successfully used for primary urethral reconstruction are the full-thickness skin graft, the bladder epithelial graft, the oral mucosal graft, and the rectal mucosal graft. Little is known about the characteristics of the rectal mucosal graft. The bladder epithelial graft and the oral mucosal graft have numerous vascular properties that make them desirable for urethral reconstruction. The issue of desiccation and hypertrophic growth, in the case of the bladder epithelial graft, has limited its use in the distal urethra.
- Full-thickness and split-thickness skin grafts have been used for penile reconstruction. The results with split-thickness skin grafts are so good that full-thickness grafts are rarely used for coverage of the penis. In complex cases, microvascular free-transfer technology has become a mainstay. For urethral reconstruction, skin islands based on the dartos fascia or tunica dartos have been effectively used. The dermal graft has been used for years to augment the tunica albuginea of the corpora cavernosa.
- The behavior of almost all forms of transfer can be predicted by examining histologic features and recognizing which layers provide which characteristics to the tissue.

Generalities of Reconstructive Surgical Techniques

With any surgical procedure, including reconstructive procedures of the external genitalia, there are basic rules and surgeons' biases regarding the best way to perform a certain operation. In this section, the differences are highlighted.

Reconstructive surgery is performed with all efforts aimed at minimizing tissue injury and promoting healing. Adequate visualization is essential. Surgical loupes are used by almost all surgeons performing adult and pediatric reconstructive genital surgery. A headlight or suction with attached light often adds to visualization, especially in deep perineal surgery. In penile cases, such as reconstruction of the fossa navicularis or correction of penile curvature, bipolar cautery is used exclusively. With cautery, the electrical charge is grounded either to a pad (monopolar) or to the opposite tong of the forceps (bipolar). In most instances, the field effects of the electricity are more confined with bipolar cautery. Because electricity is dissipated by conductors (in the case of human tissue, vessels, and nerves), there is a possibility of damage to these delicate structures. In other cases, monopolar cautery can be used in the superficial structures, but bipolar cautery is better during dissection around the corpus spongiosum, elevation of penile and scrotal flaps, division of the perineal intracorporeal space, and dissection of the dorsal neurovascular structures.

Appropriate instruments for genitourinary reconstructive surgery can commonly be found in a plastic surgery tray or on the peripheral vascular tray in the typical operating room. Some examples are fine tenotomy scissors, fine forceps, various skin hooks, and delicate needle holders. Sharp scissors that cut with minimal collateral trauma are essential. These instruments minimize tissue

Discussion of the anatomic relationships of the male genitourinary structures in the penis and male perineum must precede discussion of specific reconstructive surgical techniques; for a complete anatomic description please see Chapters 21 and 68.

The penile shaft (Fig. 40-5) comprises three erectile bodies, the two corpora cavernosa and the corpus spongiosum containing the urethra, along with their enveloping fascial layers, nerves, and vessels, all covered by skin. All of these structures continue into the perineum. The corpora cavernosa contain erectile tissue within a dense elastic sheath of connective tissue called the tunica albuginea. The corpora cavernosa are not separate structures but constitute a single space with free communication through an incompetent midline septum that becomes more complete toward the base of the penis. This erectile tissue contains arteries, nerves, muscle fibers, and venous sinuses lined with flat endothelial cells, and these features fill the corpora cavernosa, making its cut surface look like a sponge. This tissue is separated from the tunica albuginea by a thin layer of areolar connective tissue.

The third erectile body, the corpus spongiosum, lies in the ventral groove between the two corpora cavernosa. The tunica albuginea (adventitia) of the corpus spongiosum is thinner than the tunica albuginea of the corpora cavernosa, and the corpus spongiosum contains less erectile tissue than the corpora cavernosa. The urethra traverses the length of the penis within the corpus spongiosum. At its distal end, the corpus spongiosum expands to form the glans penis. The urethral meatus is slitlike, lying slightly on the ventral aspect of the tip of the glans, with its long axis oriented vertically. At its base, the penis is supported by two ligaments, composed primarily of elastic fibers that are continuous with the fascia of the penis. Posterior to this attachment, the right and left corpora cavernosa diverge, and the corpus spongiosum

broadens between the two crura to form the bulbospongiosus (bulb) (Fig. 40-6).

Figure 40-5 also illustrates the relationship of the erectile bodies and the urethra to the structures in the perineum. When discussing trauma and reconstruction, it is the consensus opinion of a World Health Organization conference convened in Stockholm in 2002 that the common use of the terms *anterior urethra* and *posterior urethra* be put aside and that the urethra be subdivided into six separate areas. These portions of the urethra are illustrated in Figure 40-7 and described as follows:

1. The **fossa navicularis** is contained within the spongy erectile tissue of the glans penis and terminates at the junction of the urethral epithelium with the skin of the glans. This portion of the urethra is lined with stratified squamous epithelium.
2. The **penile or pendulous urethra** lies distal to the investment of the ischiocavernosus musculature but is invested by the corpus spongiosum and maintains a constant lumen size roughly centered in the corpus spongiosum. The pendulous urethra is lined with simple squamous epithelium.
3. The **bulbous urethra** is covered by the midline fusion of the ischiocavernosus musculature and is invested by the bulbospongiosus of the corpus spongiosum. It becomes larger and lies closer to the dorsal aspect of the corpus spongiosum, exiting from its dorsal surface before the posterior attachment of the bulbospongiosus to the perineal body. The bulbous urethra is lined distally with squamous epithelium that gradually changes to the transitional epithelium found in the membranous urethra as it swings upward (Devine and Horton, 1977).
4. The **membranous urethra** is the portion that traverses the perineal pouch and is surrounded by the external urethral sphincter. This segment of the urethra is unattached to fixed structures, has

Figure 40-5. *Top*, Cross section of the penis at the junction of its middle and distal thirds. The septum is correctly illustrated as strands that interweave with the tunica albuginea ventrally and dorsally. *Bottom*, Diagram of a sagittal section of the penis and perineum illustrating the fascial layers. a., artery; m., muscle; n., nerve; v., vein.

Figure 40-6. Diagrammatic cross sections of the anterior urethra. A, The bulbous urethra. The urethra is eccentrically placed in the corpus spongiosum. Proximally, the corpora cavernosa have split into individual crura, with the urethra lying against the triangular ligament. B, In the shaft of the penis, the urethra is more centrally placed in relation to the corpus spongiosum, and the corpora cavernosa are intimately fused, separated only by septal fibers. C, At the coronal margin, the urethra remains relatively centrally placed, and the corpora cavernosa are fused, again separated by septal fibers. The spongy tissue of the corpus spongiosum has become incorporated as the deep tissues of the glans. D, The fossa navicularis widens in caliber and is totally surrounded by the spongy erectile tissue of the glans penis. The urethra here is relatively ventrally placed in relation to the body of the corpus spongiosum. (From Jordan GH. Complications of interventional techniques of urethral stricture disease: direct visual internal urethrotomy, stents and laser. In: Carson C, editor. Topics in clinical urology: complications of interventional techniques. New York: Igaku-Shoin; 1996. p. 86–94.)

the distinction of being the only portion of the male urethra that is not invested by another structure, and is lined with a delicate transitional epithelium.

5. The **prostatic urethra** is the portion of the urethra that is proximal to the membranous urethra and is mostly surrounded by the prostatic stromal and glandular tissue. Its epithelium is continuous with the epithelium of the trigone and bladder.
6. The **bladder neck** is the location of the bladder neck musculature, variably surrounded by intravesical protrusion of the prostate. Its epithelium is contiguous with the epithelium of the trigone and bladder.

A submucosal layer is noted throughout the length of the urethra.

Five “sphincters” are recognized (Fig. 40-8):

1. If one begins proximally, the bladder neck is first.
2. The prostate itself is composed of a muscular stroma.
3. The prostate muscle continues into the membranous urethra as the external smooth muscle sphincter.
4. The external rhabdosphincter is often referred to as the external sphincter.
5. In the area of the membranous urethra are the muscles of recruitment, which are not true sphincters but provide aid with volitional continence.

In the penis, the erectile bodies are surrounded by Buck fascia, dartos fascia, and skin. Buck fascia is the tough, elastic layer immediately adjacent to the tunica albuginea (see Fig. 40-5). On the superior aspect of the corpora cavernosa, the deep dorsal vein, paired dorsal arteries, and multiple branches of the dorsal nerves are contained within the envelope of Buck fascia. In the midline groove on the underside of the corpora cavernosa, Buck fascia splits to surround the corpus spongiosum. Consolidation of the fascial layers (Fig. 40-9), lateral to the corpus spongiosum, attaches it to the tunica albuginea of the corpora cavernosa. Attached distally to

Figure 40-7. Sagittal section of the pelvis. The urethra is subdivided into the following sections: 1, fossa navicularis; 2, pendulous or penile urethra; 3, bulbous urethra; 4, membranous urethra; 5, prostatic urethra; and 6, bladder neck. By common usage, the divisions of the fossa navicularis, pendulous urethra, and bulbous urethra compose the anterior urethra, and the divisions of the membranous urethra, prostatic urethra, and bladder neck compose the posterior urethra. (Modified from Devine CJ Jr, Angermeier KW. Anatomy of the penis and male perineum. AUA Update Series 1994;8:11.)

Figure 40-8. Diagrammatic representation of the sphincters surrounding the male posterior urethra.

the undersurface of the glans penis at the corona, Buck fascia extends into the perineum, enclosing each crus of the corpora cavernosa and the bulb of the corpus spongiosum, and firmly fixing these structures to the pubis, ischium, and inferior fascia of the perineal membrane (urogenital diaphragm).

Distally, the skin of the penis is confluent with the glabrous skin covering the glans. At the corona, it is folded on itself to form the foreskin (prepuce) that overlies the glans. The dartos fascia, a layer of areolar tissue remarkable for its lack of fat, separates these two layers of skin and continues into the perineum, where it fuses with the layers of the superficial perineal (Colles) fascia. In the penis, the dartos fascia is loosely attached to the skin and the deeper layer of Buck fascia and contains the superficial arteries, veins, and nerves of the penis.

Blood is supplied to the skin of the penis by the left and right superficial external pudendal vessels (Fig. 40-10A), which arise from the first portion of the femoral artery, cross the upper medial portion of the femoral triangle, and divide into two main branches, running dorsolaterally and ventrolaterally in the shaft of the penis, with collateralization across the midline. At intervals, fine branches split off to the skin, forming a rich subdermal vascular plexus that can sustain the skin after its underlying dartos fascia has been mobilized. The arteries are accompanied by venous tributaries that are more prominent and more easily seen than the arteries. Because of its remarkable thinness and mobility and the character of its vascular supply, the skin covering the penis is an ideal substitute—in some cases, for urethral reconstruction. The blood supply to the scrotal wall and ventral penile skin is based on the posterior scrotal artery, a superficial vessel from the deep internal pudendal artery (Fig. 40-10B). As with the superficial external pudendal tributaries, the posterior scrotal system provides a series of tributaries carried within the tunica dartos.

Venous Drainage

The penis is drained by three venous systems: superficial, intermediate, and deep (Fig. 40-11) (Aboseif et al, 1989). The superficial veins contained in the dartos fascia on the dorsolateral aspects of the penis unite at its base to form a single superficial dorsal vein. The superficial dorsal vein usually drains into the left saphenous vein (rarely into the right) and occasionally forms two trunks that drain into both. Veins from more superficial tissue may drain into the external superficial pudendal veins.

The intermediate system contains the deep dorsal and circumflex veins, lying within and beneath Buck fascia. Emissary veins begin within the erectile space of the corpora cavernosa and, following a perpendicular or oblique course through the tunica albuginea, emerge from the lateral and dorsal surfaces of the corpora cavernosa to empty into the circumflex veins or the deep dorsal vein. The circumflex veins are channels, usually more prominently present in the distal two thirds of the penile shaft. They arise from the corpus spongiosum, on the ventrum of the penis, and often receive the emissary veins as they travel around the lateral aspect of the corpora cavernosa, passing beneath the dorsal arteries and nerves to empty into the deep dorsal vein. The circumflex veins can also become confluent ventrally, forming periurethral veins on each side. These may become important in the treatment of impotence caused by veno-occlusive incompetence.

The deep dorsal vein is formed by five to eight small veins emerging from the glans penis to form the retrocoronal plexus, which drains into the deep dorsal vein that may consist of more than one vein lying in the midline groove between the corporeal bodies. In many patients, there is a connection between the superficial and deep dorsal veins. The vein gathers blood from the emissary and circumflex veins, and passing beneath the pubis at the level of the suspensory ligament, it leaves the shaft of the penis at the crus and drains into the periprostatic plexus.

The deep drainage system consists of the crural and cavernosal veins. The crural veins arise in the midline, in the space between the crura. Normally, they are small and almost indiscernible, joining the deep dorsal vein or the periprostatic plexus. If the deep dorsal vein has been ligated or obliterated after trauma, striking development of these veins can be noted as the intracanal space is entered during the perineal dissection for urethral repair. Emissary veins in the proximal third of the crura, near their attachment to the ischial tuberosities, join to form several thin-walled trunks on the dorso-medial surface of each corpus cavernosum. Some pass medially, joining the dorsal or crural veins, or, extending proximally, enter the periprostatic plexus. Most consolidate into one or two cavernosal veins on each side. Running in the penile hilum, deep and medial to the cavernosal arteries and nerves, they join to form a large venous channel that drains into the internal pudendal vein. Three or four small cavernosal veins emerge from the dorsolateral surface of each crus and course laterally between the bulbospongiosus and the crus of the penis for 2 to 3 cm before draining into the internal pudendal veins. These usually insignificant vessels become larger and can be noted more readily in patients with veno-occlusive erectile dysfunction. The internal pudendal veins (usually two) run together with the internal pudendal artery and nerve in the Alcock canal to empty into the internal iliac vein.

Arterial System

The blood supply to the deep structures of the penis is derived from the common penile artery, which is a continuation of the internal pudendal artery after it gives off the perineal branch (Fig. 40-12). From that point, the artery is termed the *common penile artery* and travels along the medial margin of the inferior pubic ramus. As it nears the urethral bulb, the artery divides into its three terminal branches, the bulbourethral artery, dorsal artery, and cavernosal artery.

The bulbourethral artery is a short artery or arteries of relatively large caliber that pierce the Buck fascia to enter the bulbospongiosus. These arteries are oriented almost parallel to the path of the membranous urethra.

The dorsal artery generally travels along the dorsum of the penis between the deep dorsal vein medially and the dorsal nerves laterally, with a coiled rather than a straight configuration. The artery uncoils as the penis elongates with erection, allowing flow to be maintained. Along its course, it gives off 3 to 10 circumflex branches (the circumflex cavernosal arteries) that accompany the circumflex veins around the lateral surface of the corpora cavernosa and provide vascularity to the corpus spongiosum. Its terminal branches arborize in the glans penis. In many patients, branches

Figure 40-9. Cross sections of the pelvis. A, The normal attachment of the fasciae enveloping the penile structures. The dartos fascia is contiguous with the Scarpa fascia onto the abdomen, with the tunica dartos of the scrotum, with the Colles fascia on the perineum, and over the thigh—eventually to insert at the fascia lata. B, With trauma to the pelvis or perineum, the corpus spongiosum is injured; however, the hematoma is confined by the attachment of the Buck fascia. C, With trauma to the perineum or pelvis, the corpus spongiosum is injured, and the Buck fascia is violated; the hematoma can spread throughout the confines of the extended dartos fascia–tunica dartos system.

Figure 40-10. The vasculature to the genital skin. A, The superficial external pudendal vessels arborize to become the fascial blood supply contained in the dartos fascia of the penis. B, The scrotal artery is a terminal branch of the deep internal pudendal artery. This artery is thought to arborize in the tunica dartos of the scrotum and Colles fascia of the perineum. The perineal artery continues lateral to the groin crease onto the thigh and extends toward the groin. a., artery; v., vein.

Figure 40-11. The venous drainage of the deep structures of the penis. (From Horton CE, Stecker JF, Jordan GH. Management of erectile dysfunction, genital reconstruction following trauma and transsexualism. In: McCarthy JG, editor. Plastic surgery, vol 6. Philadelphia: Saunders; 1990. p. 4213–45.)

Figure 40-12. The arterial supply to the deep structures of the penis. (From Horton CE, Stecker JF, Jordan GH. Management of erectile dysfunction, genital reconstruction following trauma and transsexualism. In: McCarthy JG, editor. Plastic surgery, vol 6. Philadelphia: Saunders; 1990. p. 4213–45.)

penetrate the tunica and connect to the cavernosal arteries. The functional significance of these perforators varies from individual to individual.

The cavernosal artery, usually a single artery, arises on each side as the terminal branch of the penile artery. It enters the corpus cavernosum at the hilum and runs the length of the penile shaft, splitting off the many helicine arteries that constitute the arterial portion of the erectile apparatus. The arteries frequently branch before entering the corporeal body. Sometimes a branch enters the opposite corpus cavernosum, and occasionally a single artery branches in the penile shaft to supply both sides.

Lymphatics

Lymph drainage from the glans penis collects in large trunks in the area of the frenulum. The lymph vessels circle to the dorsal aspect of the corona, where they unite with vessels from

the other side. The vessels traverse the penis beneath Buck fascia, terminating mostly in the deep inguinal lymph nodes of the femoral triangle. Some drainage is to the presymphyseal lymph nodes and by way of these to the lateral lymph nodes of the external iliac group.

Nerve Supply

The nerves of the penis are derived from the pudendal and cavernosal nerves. The pudendal nerves supply somatic motor and sensory innervation to the penis. The cavernosal nerves are a combination of the parasympathetic and visceral afferent fibers and constitute the autonomic nerves of the penis. These provide the nerve supply to the erectile apparatus.

The pudendal nerves enter the perineum with the internal pudendal vessels through the lesser sciatic notch at the posterior border of the ischiorectal fossa. They run in the fibrofascial pudendal Alcock canal to the edge of the urogenital diaphragm. Each dorsal nerve of the penis arises in the Alcock canal as the first branch of the pudendal nerve. Traveling ventral to the main pudendal trunk above the internal obturator and under the levator ani, the dorsal nerves perforate the transverse perinei muscles to arrive on the dorsum of the penis and continue distally along the respective dorsolateral penile surface lateral to the dorsal artery. On the shaft, their fascicles fan out to supply proprioceptive and sensory nerve terminals in the tunica of the corpora cavernosa and sensory terminals in the skin. These nerves terminate in the glans penis.

Perineum

The perineum is the diamond-shaped outlet bounded anteriorly by the pubic arch and the arcuate ligaments of the pubis, posteriorly by the tip of the coccyx, and laterally by the inferior rami of the pubis and ischium. A transverse line between the ischial tuberosities divides the perineum into an anterior triangle containing the external urogenital organs and a posterior anal triangle (Fig. 40-13A and B).

Colles Fascia. In the anterior triangle, Colles fascia (see Fig. 40-13A) attaches at its posterior margin to the perineal body at the posteroinferior margin of the urogenital diaphragm. The fascia curves below the superficial transverse perinei muscles and projects forward as two layers attached laterally to the ischium and the inferior ramus of the pelvis. The loose superficial layer is fatty and is continuous with the more substantial dartos fascia (tunica dartos) of the scrotum. In the scrotum, the dartos fascial layer contains muscle fibers that cause the rugose appearance of the scrotum. The fascia also projects (but without muscle fibers) into the midline to form the septum between the halves of the scrotum. The median raphe in the skin delineates the separation of the halves of the scrotum and is continued anteriorly as a darkly colored streak in the ventral midline of the penis and posteriorly as the median raphe of the perineum terminating at the anus.

The deep membranous layer of Colles fascia is a more substantial layer that forms a roof over the scrotal cavity, separating it from the superficial perineal pouch. At the anterior aspect of the scrotum, Colles fascia joins with the dartos fascia (tunica dartos) of the scrotum, and a fold of this fascia projects backward beneath the fibers of the midline fusion of the ischiocavernosus muscle (bulbospongiosus muscle). At the base of the penis, it is continuous with the dartos fascia of the penis. Thickenings of the fascia at this level form the two suspensory ligaments of the penis. First, the outer fundiform ligament, which is continuous with the lower end of the linea alba, splits into laminae that surround the body of the penis and unite beneath it. Second, the inner triangle-shaped suspensory ligament is attached to the anterior aspect of the symphysis pubis and blends with the dartos fascia of the penis below it.

Anteriorly, Colles fascia fuses and becomes continuous with the membranous layer of the subcutaneous connective tissue of the anterior abdominal wall (Scarpa fascia). Laterally, Colles fascia

Figure 40-13. “Peel-away” diagrams of the anatomy of the perineum. **A**, The skin and subcutaneous tissues have been removed. **B**, In the anterior perineal triangle, Colles fascia has been removed. In the posterior anal triangle, the pelvic diaphragm has been removed. Note the division of the superficial transverse perineal muscle, exposing the deep transverse perineal muscle.

Figure 40-13, cont'd C, The anterior perineal triangle has been dissected to expose the erectile bodies. **D,** The corpus spongiosum has been divided at the departure of the urethra from the penile bulb. The intracanal space is exposed. (From Devine CJ Jr, Angermeier KW. *Anatomy of the pelvis and male perineum*. AUA Update Series 1994;13:1015.)

fuses to the pubic arch and with the fascia lata. Posteriorly, Colles fascia sweeps beneath the transverse perineal muscles, fusing with the posterior aspect of the perineal membrane. The space beneath the continuous plane formed by these fascial attachments is the superficial perineal pouch, in which infections or extravasation of urine and collections of blood (after trauma to the urethra) may be confined (see Fig. 40-9).

Superficial Perineal Space. In males, the superficial perineal space contains the continuation of the corpora cavernosa, the proximal part of the corpus spongiosum and urethra, the muscles associated with them, and the branches of the internal pudendal vessels and pudendal nerves (see Fig. 40-13B). The

ischiocavernosus muscles cover the crura of the corpora cavernosa. They attach to the inner surfaces of the ischium and ischial tuberosities on each side and insert at the midline into Buck fascia, surrounding the crura at their junction below the arcuate ligament of the penis. **The midline fusion of the ischiocavernosus muscles and bulbospongiosus muscles is in the midline of the perineum.** They are attached to the perineal body posteriorly and to each other in the midline, as they encompass the bulbospongiosus and crura of the corpora cavernosa at the base of the penis. These muscles are confluent with the ischiocavernosus muscles laterally and at their insertion into Buck fascia, covering the dorsal vessels and nerves at the base of the penis.

Central Perineal Tendon (Perineal Body). Lying just anterior to the anus, as a part of the plane separating the anterior and posterior perineal triangles, the **perineal body** is formed by the interconnection of eight muscles of the perineum (see Fig. 40-13A and B). The perineal body receives fibers from the anterior portion of the anal sphincter and is the central point of insertion of the superficial transverse perineal muscles that arise at the ischial tuberosities. The bulbospongiosus muscle (midline fusion of the ischiocavernosus muscle) is fixed to the perineal body by its most posterior fibers. The deep transverse perineal muscles and fibers from the anterior portions of the levator ani muscles attach to the deep aspect of the perineal body.

Deep Perineal Space. The urogenital diaphragm constitutes the deep perineal space (see Fig. 40-13C and D). It is contained within two layers of fascia and incompletely covers the outlet of the pelvis anterior to the deep layer of the perineal body. The deep layer of fascia is an indistinct structure—the continuation of the endopelvic obturator fascia. The superficial fascia attaches laterally to the ischial rami and the inferior ramus of the pubis. This fascia blends with the deep layer behind the perineal body and anteriorly, where it terminates with a thickened edge, the transverse perineal ligament. A space between this ligament and the arcuate ligament of the pubis accommodates the deep dorsal vein of the penis.

The deep perineal pouch (see Fig. 40-13D) contains the deep transverse perineal muscles, the external sphincter of the urethra, the bulbourethral (Cowper) glands, and the blood vessels and nerves associated with the structures within it. The sphincter urethral muscle fibers arise from the medial surface of the inferior pubic rami and pass medially toward the urethra, where they meet the fibers from the opposite side. In males, the muscle encircles the membranous urethra to function as the somatic sphincter of the urethra (Haertsch, 1981).

KEY POINTS: ANATOMY OF THE PENIS AND MALE PERINEUM

- An understanding of the anatomy is of utmost importance to the surgeon. The penile shaft is composed of three erectile bodies: the paired corpora cavernosa and the corpus spongiosum. The corpus spongiosum invests the anterior urethra.
- By consensus, the urethra has been subdivided into six separate areas: the fossa navicularis, the penile or pendulous urethra, the bulbous urethra, the membranous urethra, the prostatic urethra, and the bladder neck.
- In the male, five urethral “sphincters” are recognized. If one begins proximally, there is the bladder neck. The prostate itself is composed of a muscular stroma. The prostatic muscle continues into the membranous urethra as the external smooth muscle sphincter. The external rhabdosphincter is often referred to as the external sphincter, and in the area of the membranous urethra are the muscles of recruitment that are not true sphincters.
- The Buck fascia is devoted to the deep structures of the penis. The more areolar and superficial fascia, the dartos fascia, is related more to the skin and its vasculature.
- The blood supply to the deep structures of the penis is based on the common penile artery, which is the extension of the deep internal pudendal artery. The blood supply to the skin of the genitalia is based on the perineal branch—scrotal branch of the deep internal pudendal artery and the superficial external pudendal vessels, branches of the femoral arteries. The penis is drained by three systems: the superficial, intermediate, and deep venous systems.
- The nerves to the penis are derived from the pudendal and the cavernosal nerves. The pudendal nerve supplies somatic motor and sensory innervation to the penis. The cavernosal nerves are a combination of the parasympathetic and the visceral afferent fibers and constitute the autonomic nerves to the penis.
- The perineum is a diamond-shaped outlet bounded anteriorly by the pubic arch and the circuate ligaments of the pubis, posteriorly by the tip of the coccyx, and laterally by the inferior rami of the pubis and ischium. A transverse line between the ischial tuberosities divides the perineum into an anterior triangle containing the external urogenital organs and a posterior anal triangle.

injury from manipulation and permit more precise dissection. For urethral surgery, a set of bougie à boule sizers is essential to check the caliber of the urethral lumen. McCrea urethral sounds are a good addition to the typical van Buren sounds available in the usual operating room. For calibration, sounds do not replace the need for bougie à boule calibrators. For posterior urethral reconstruction, a sound to pass through the cystostomy tract and prostate to find the proximal end for the reconstruction is often helpful. We find that a Haygrove staff serves this role nicely. Some centers use the cystoscope for this purpose, and often it suffices well, whereas at other times it is not as effective as the Haygrove-style sound.

The choice of suture material evolves on the basis of the surgeon's experience and bias. However, there are some common principles with which most surgeons would agree. First, in urethral surgery, absorbable suture is the rule. Typical choices for most surgeons are braided absorbable sutures or the family of monofilament absorbable sutures. Chromic suture is rarely used now because the choices of other absorbable sutures seem superior in virtually all cases. In the case of tension-free closures, very small sutures can be used. In some cases, tying the suture can be awkward, and a larger suture may be warranted, even though the anastomosis is tension free. The caliber of suture should be the smallest possible to line up the tissue, which is typically not under tension. There is no reason to use suture that is stronger than the tissues that are being sutured. Fine suture such as 5-0 and 6-0 chromic or polyglactin can be used to suture the epithelium to the adventitia of the corpus spongiosum to control bleeding. For a flap or graft repair, 4-0 to 6-0 suture is usually adequate. For primary anastomosis of the corpus spongiosum or for a posterior urethral reconstruction, 3-0 suture may be appropriate because of tying concerns. The needle should be tapered if possible except when, as in urethroplasty, for example, severe spongiofibrosis or scarring is present. Some typical choices are taper needles, such as RB-1, TF, and SH-1, and cutting needles, such as P-3 and PC-3. The UR-6 half-circle taper needle that is often used in radical prostatectomy can be helpful for deep perineal anastomosis of the urethra.

Surgical position and retraction are critical to attaining good results. If possible, procedures are done with the patient supine or prone. Many procedures that previously were done with the patient in the lithotomy position can be done with the patient in the frog-leg or split-leg position. For penile surgery, a Scott retractor with stay hooks (Lone Star Medical Products, Houston, TX, the Jordan-Bookwalter perineal retractor set (C. S. Surgical, Slidell, LA; J. Hugh Knight Instrument Company, New Orleans, LA), or the Omni-Tract perineal retractor (Omni-Tract Surgical, Division of Minnesota Scientific, St. Paul, MN) is helpful. Lithotomy or exaggerated lithotomy positions are used only for the minimal time necessary. With appropriate padding for the foot and positioning without pressure on the back of the leg, complications in the low-lithotomy position are minimal. When the patient is in the supine, split-leg, and low-lithotomy positions, venous compression stockings can be used. The controversy in positioning revolves around the use of the exaggerated lithotomy position. We prefer to use this position for all bulbar and posterior urethral reconstructions. Other surgeons use a lower lithotomy position. We find the more exaggerated position to be safe and believe that it provides unequalled access to the deep perineal structures (Angermeier and Jordan, 1994). Details of positioning, as we do it, are described later. To minimize the patient's time in the exaggerated position, all graft harvesting or flap elevation is done with the patient in the flat supine position.

In addition to proper diagnosis and planning, the surgical technique is important for the overall success of reconstructive surgery. In contrast to the results of extirpative surgery, the results of reconstructive surgery depend on methods that minimize tissue damage and maximize wound healing. The key ingredients are adequate visualization, appropriate choice of suture, delicate tissue handling, appropriate positioning, and adequate retraction.

KEY POINTS: RECONSTRUCTIVE SURGICAL TECHNIQUES

- Reconstructive surgery is performed with all efforts aimed at minimizing tissue injury and promoting healing. Loupe magnification is used by almost all surgeons performing adult and pediatric reconstructive surgery. For deep exposure, a headlight or lighted suction is advantageous. Instruments must be delicate because reconstructive surgery employs small sutures and small needles.
- The choice of suture material evolves on the basis of the surgeon's experience. However, the caliber of sutures should be the smallest possible to align the tissue, which is not typically under tension. There is no reason to use suture that is stronger than the tissues being sutured.
- The choice of surgical positioning is left to the surgeon's preference.
- Proper diagnosis and planning of the surgical technique are important for the success of reconstructive surgery.

SELECTED PROCESSES

Urethral Hemangioma

Although **urethral hemangioma** is a rare condition, it is usually **persistent** and offers a challenge to the surgeon when excision is deemed necessary. Patients typically present with hematuria or a bloody urethral discharge and occasionally with obstructive symptoms. The lesions may be single or multiple, and the urethral meatus is a common location. Although the diagnosis is often made with cystoscopy, which readily visualizes the dilated blood vessels, the lesion often extends beyond the point at which it is seen with cystoscopy.

Because all reported cases of urethral hemangioma have been benign, management depends on the size and location of the lesion. Asymptomatic lesions do not require treatment and should be observed because hemangiomas can regress spontaneously. Symptomatic lesions that require treatment must be completely excised to prevent recurrence.

Although electrofulguration has been reported as a possible treatment of urethral hemangioma, it should be used only to control an acute episode. For smaller lesions, laser treatment has been successful and produces less scarring. Lasers that are used for this purpose include argon, potassium titanyl phosphate (KTP) (532 nm), and neodymium:yttrium-aluminum-garnet (Nd:YAG). The preferred treatment of larger lesions is open excision and urethral reconstruction; in some cases, this means circumferential reconstruction. Tubed graft reconstruction should be avoided; tubed flap reconstruction or tubed construction with mixed tissue transfer could be considered, although staged reconstruction is probably preferable. In addition, good initial success has been reported with polidocanol as a sclerosing agent for extensive urethral hemangiomas.

Reactive Arthritis

Reactive arthritis is characterized by a classic triad of arthritis, conjunctivitis, and urethritis. In addition, some patients have had an episode of diarrhea that preceded the development of arthritis. However, the classic triad is not present in most cases, and patients present with only arthritis affecting the knees, ankles, and feet in an asymmetrical distribution. The history of urethritis is obtained on detailed questioning.

Urethral involvement is usually mild and self-limited and constitutes a minor portion of the disease. In approximately 10% to 20% of patients, a glanular lesion is present. Referred to as **circinate balanitis**, this lesion is **diagnostic of reactive arthritis** and typically appears as a shallow, painless ulcer with gray borders. Occasionally, the lesion appears as small, red macules, 1 to 2 mm

in diameter. When the urethritis is mild and self-limited, no treatment is necessary.

In rare cases, urethritis causes severe inflammation with necrosis of the mucosa, producing uncompromising stricture disease. We have been unsuccessful in excision and replacement of the urethra in these cases. Alternatively, we perform a perineal urethrostomy and excise the entire distal urethra. This approach may decrease the rheumatic manifestations associated with reactive arthritis.

Lichen Sclerosus

Lichen sclerosus (LS) was previously known as balanitis xerotica obliterans. LS is a chronic inflammatory hypomelanotic, lymphocyte-mediated skin disorder that in men involves the prepuce and glans and frequently leads to meatal stenosis and possible urethral involvement.

The reported incidence of LS in the Western population is 1 per 300 persons; however, the worldwide prevalence may be substantially different (Wallace, 1971; Dogliotti et al, 1974; Jacyk and Isaac, 1979; Datta et al, 1993). The peak ages of recognition in women are bimodal, with many cases noted before puberty and with another peak occurring in postmenopausal women (Tasker and Wojnarowska, 2003). In men, LS seems to peak between ages 30 and 50; however, LS has been described in people of all ages, from infants to elderly adults (Tasker and Wojnarowska, 2003). LS is commonly found at the time of circumcision when performed after the neonatal period (McKay et al, 1975; Rickwood et al, 1980; Garat et al, 1986; Ledwig and Weigand, 1989; Meuli et al, 1994). **LS is the most common cause of meatal stenosis and appears as a whitish plaque that may involve the prepuce, glans penis, urethral meatus, and fossa navicularis. If only the foreskin is involved, circumcision may be curative (Akpioraye et al, 1997).** In our experience, LS usually begins as a meatal or perimeatal process in a circumcised patient, but it may involve other areas of the preputial space in uncircumcised patients. In uncircumcised men, the prepuce becomes edematous and thickened and often may be adherent to the glans (Bainbridge et al, 1971). Diagnosis is made with biopsy. Several reports have suggested an association with chronic infection by a spirochete, *Borrelia burgdorferi* (Tuffanelli, 1987; Dillon and Ghassan, 1995; Shelley et al, 1999).

The first report of what was probably LS was published by Weir in 1875. He described a case of vulvar and oral "ichthyosis" (Weir, 1875). The term *balanitis xerotica obliterans* was first applied by Stühmer in 1928. Freeman and Laymon showed that balanitis xerotica obliterans and LS were probably the same process (Freeman and Laymon, 1941; Laymon and Freeman, 1944). In 1976, the International Society for the Study of Vulvar Disease devised a new classification system unifying the nomenclature and proposed the term *lichen sclerosus* (Friedrich, 1976).

The cause of LS has not been defined. Many mechanisms have been proposed. Koebner phenomenon relates the development of LS to trauma to an affected area (Lee and Phillips, 1994). A proposed mechanism is an autoimmune event. Autoantibodies to extracellular matrix protein 1 (ECM1) were detected in the serum of 67% of patients with LS and only 7% of control subjects, which would imply an autoimmune process (Oyama et al, 2003). Reports of LS associated with vitiligo, alopecia areata, thyroid disease, and diabetes mellitus also suggest a possible autoimmune basis. Reported oxidative damage of lipids, DNA, and protein in patients with LS may explain the mechanism of sclerosis, autoimmunity and carcinogenesis of LS (Sander et al, 2004).

An infectious cause was previously implicated (Tuffanelli, 1987; Ross et al, 1990), but a more recent case-control series found no association (Edmonds and Bunker, 2010). It has also been proposed that LS has a genetic origin, based on the observation of a familial distribution of cases (Marren et al, 1995). There have been reports of concomitant existence of the disease in identical twins (Thomas and Kennedy, 1986; Fallic et al, 1997) and nonidentical twins (Cox et al, 1986), with coexistence of dermatosis. The disease also has been seen in mothers and daughters (Shirer and Ray, 1987). Studies

on the human leukocyte antigen (HLA) have suggested a genetic component in patients with LS (Marren et al, 1995).

The combination of topical steroids and antibiotics may help stabilize the inflammatory process. Conservative therapy may be warranted in patients whose meatus can easily be maintained at 14 to 16 French (Staff, 1970). In these cases, intermittent catheterization with lubrication of the catheter and meatal dilator with 0.05% clobetasol (Temovate) may be adequate treatment. Long-term antibiotic therapy may also be helpful to improve inflammation because secondary infection of the inflamed tissue may occur. We have typically used tetracycline, but a trial of long-term penicillin or advanced-generation erythromycin therapy may be warranted (Shelley et al, 1999). This nonsurgical approach to treatment is used in patients who are not good surgical candidates for other medical reasons or in older patients and in younger patients who demonstrate stable disease. Secrest and colleagues (2008) proposed a link between hypogonadism and LS in male patients. These authors consistently showed diminished testosterone levels in patients with LS and analyzed whether replacement androgen therapy would be helpful.

Surgery is indicated in young patients with severe meatal stenosis. Because patients with long-standing meatal stenosis often have severe proximal urethral stricture disease, retrograde urethrography should be performed before therapy is initiated. A simple meatotomy is generally ineffective in patients with LS. Morey and colleagues (2007) showed that an extended meatotomy in patients with refractory stenosis was successful in 14 of 16 patients (87%). Malone (2004) described a ventral/dorsal meatotomy with an inverted V-shaped relaxing incision with the apex of the V close to the proximal limit of the dorsal meatotomy.

The etiology of stricture disease associated with LS is unclear. Possible causes include iatrogenic stricture resulting from repeated instrumentation and pressure voiding associated with meatal stenosis causing secondary intravasation of urine into the glans Littre (Fig. 40-14). In cases of early LS with only meatal involvement resulting in stenosis of the fossa navicularis, prompt reconstruction seems to be successful in the long-term and seems to avoid the sequelae of panurethral stricture disease. Most surgeons believe that because LS is a disease of genital skin, better tissue for reconstruction is the oral mucosa; techniques are discussed later (Mundy, 1994; Bracka, 1999). Long-standing cases with a long length of urethral stricture are amenable to techniques of reconstruction but are very challenging. It seems that except in the case of urethral stricture disease confined only to the meatus and fossa navicularis, staged oral graft reconstruction, at least in the short-term to mid-term, seems to provide superior durable results. This may also be true in cases confined to the meatus and fossa navicularis because an analysis of patients reconstructed with the ventral transverse skin island technique showed a 50% recurrence rate even in those patients; the weakness of this analysis is that the data did not include biopsy proof that all patients had LS (Virasoro et al, 2007). We also see patients who present with a buried penis. This phenomenon occurs when the skin of the penile shaft has been lost because of severe inflammation, and the penis is trapped in the penopubic and scrotal area. These patients are often profoundly overweight, and many are diabetic; they have often had prior surgical procedures. Management of these patients is complex and ultimately determined by their desire and need for functional reconstruction. In some patients with severe urethral stricture disease, we have completely reconstructed the urethra; in others, we have simply performed a perineal urethrostomy. Perineal urethrostomy is usually technically straightforward because the rule in most patients with LS is to spare the proximal anterior urethra. We have proposed that, in many cases, the sparing of the proximal anterior urethra demonstrates the distribution of the glands of Littre for a given patient. Younger patients have requested mobilization and release of the penis with placement of a split-thickness skin graft. However, because the inflammation involves the glans penis (which is not removed), the secondary inflammation may also involve the skin graft. Lifelong monitoring of these patients for the secondary effects of inflammation is necessary.

Figure 40-14. A and B, Urethrography in a patient with urethral stricture disease associated with lichen sclerosus. The intravasation of contrast material into the dilated glands of Littre during voiding is illustrated. (From Jordan GH. Management of membranous urethral strictures via the perineal approach. In: McAninch J, Carroll P, Jordan GH, editors. Traumatic and reconstructive urology. Philadelphia: Saunders; 1996.)

Finally, several reports have suggested the development of squamous cell carcinoma in patients with a long history of LS (Doré et al, 1990; Pride et al, 1993).

Amyloidosis

Amyloidosis of the urethra, although a rare disease, should be considered in the evaluation of any patient with a urethral mass. Patients may present with hematuria, dysuria, or urethral obstruction. Because the differential diagnosis includes urethral neoplasm, cystoscopy with transurethral biopsy is indicated. When the diagnosis is made, treatment should be based only on symptoms. Most patients can be observed expectantly and do not require aggressive treatment. Some patients require treatment for urethral stricture. Progression and recurrence are rare (Walzer et al, 1983; Dounis et al, 1985; Crook et al, 2002).

Urethrocutaneous Fistula

A urethrocutaneous fistula is a tract lined with epithelium that leads from the urethra to the skin. The size of a fistula can vary from pinpoint to large. Urethral fistulae may be a complication of urethral surgery or develop secondary to periurethral infection associated with inflammatory strictures or treatment of a urethral growth (condyloma or papillary tumor). Treatment of a urethral fistula must be directed not only to the defect but also to the underlying process that led to its development. Treatment varies according to the cause of the fistula. In cases of urethral reconstruction, especially reconstruction for hypospadias, fistula often occurs or recurs because of distal obstruction and high-pressure voiding. Additionally, in some cases in which multiple attempts at fistula closure have been attempted and failed, the tissues adjacent to the fistula are so scarred that staged reconstruction is needed to import "better tissue."

After urethral surgery, fistulae can develop immediately or as delayed complications. An early fistula is the result of poor local healing, possibly secondary to hematoma, infection, or tension with closure. In addition, breakdown of the urethra or overlying skin closure, or both, could occur. Very occasionally, with aggressive local care and continued urinary diversion, the fistula closes spontaneously.

Several techniques are used for fistula closure. Endoscopic and radiographic evaluation of the urethra must be performed before

the repair in all cases. If the fistula is small and closure of the hole does not decrease the lumen of the urethra, a button of skin is removed from around the fistula, and its edges are cut flush with the urethral wall. The urethra is closed with small (6-0 or 7-0) absorbable sutures, inverting the epithelial edge, and the repair is tested to ensure that it is watertight. We prefer either polyglycolic acid (Vicryl) or polydioxanone suture. Subsequent layers are designed and closed to avoid superimposed suture lines. Without question, the safest diversion is a suprapubic catheter. However, in many cases, a silicone stent that reduces pressure during voiding for 7 to 14 days suffices. The operating microscope can be useful for the closure of small fistulae, allowing the use of 8-0 polyglycolic acid suture and limiting the size of the associated skin incision.

If the fistula is so large that simple closure would compromise the lumen of the urethra, local flaps often are required. However, if the adjacent tissues are thin and poorly visualized, closure of the fistula may become a staged urethral reconstruction as mentioned earlier. For larger fistulae, a suprapubic tube for diversion is probably prudent. Mobilization of flaps, such as the tunica dartos flap, may be necessary to secure adequate tissue interposition and avoidance of superimposed suture lines.

Fistulae associated with inflammatory strictures occur as periurethral tracts and develop secondary to high-pressure voiding of infected urine. As multiple tracts develop, this problem becomes what is known as a "watering pot perineum." Repair requires suprapubic drainage, and treatment of the infection requires incision and drainage of any abscesses present. We widely excise the fistula tracts and associated inflammatory tissue and wait 4 to 6 months before repairing the underlying stricture. Flap reconstruction, if donor tissues are available, may be used. However, a staged graft procedure (discussed later) is also an excellent choice. One must be cautious in a patient with urethral fistulae but without a history of chronic obstructive voiding symptoms. In many cases, fistula or periurethral abscess may be the hallmark symptom of urethral carcinoma.

Urethral Diverticulum

A congenital diverticulum is a transitional cell epithelium-lined pouch that is the result of either a distention of a segment of the urethra or the attachment of a structure to the urethra by a narrow neck (i.e., a müllerian remnant). In male patients, a congenital anterior urethral diverticulum may result from incomplete development of the urethra, with a defect in only the ventral

wall and subsequent distention of this segment by the hydraulic force of the voiding stream (Valdivia et al, 1986; Bedos and Cibert, 1989; Ozgok et al, 1994). The downstream lip of the defect may serve as a valvular obstruction, increasing the pressure in the lumen, and subsequently the diverticulum enlarges. **Another possible etiology is injury of the urethra, which may cause an intraspongiosal hematoma.** This hematoma could create a paraurethral space and subsequent diverticulum or fistula. These defects can also be associated with urethral strictures (Bryden and Gough, 1999). It has also been suggested that congenital diverticula may represent giant cystic dilation of Cowper ducts (Gil-Vernet, 1977; Jiminez Cruz and Rioja Sanz, 1993). We do not favor this proposed suggested etiology because the diverticula seem to be slightly more distal than the expected location of Cowper ducts, and in our experience with reconstruction of a considerable number of these diverticula, no proximal limb of the ducts seems to exist in them. In many cases, endoscopic unroofing of the diverticulum remedies the voiding symptoms; although after unroofing, the patient commonly may note postvoid dribbling. Open repair essentially excises the redundancy of the urethra associated with the diverticulum. If the lumen is compromised, dorsal onlay by either graft or flap can be useful.

A congenital diverticulum in the prostatic urethra may be a large remnant of the müllerian duct associated with defects of diminished virilization. However, it often occurs in proximal hypospadias and represents an enlarged utricle (Devine et al, 1980). These diverticula may not be demonstrated with voiding urethrography but are demonstrated with cystoscopy or retrograde urethrography. The tip of a urethral catheter tends to catch in this opening, necessitating the use of something to direct the catheter tip toward the true lumen. Other than necessitating caution during evaluation, these diverticula do not usually cause problems or require treatment unless they are very large.

Large utricles can accumulate urine with voiding and then decompress after voiding. If they are large enough, the stasis of urine can be associated with recurrent urinary tract infection or difficult-to-manage "incontinence." A surgical approach to small lesions can be through a suprapubic incision, possibly opening the bladder to go through the center of the trigone. However, large diverticula can be approached trans-sacally (Peña and Devries, 1982). Although this is a complex procedure, it seems to be associated with much less morbidity than an abdominal or a perineal approach and provides superior exposure. We excise the diverticulum after exposing and dissecting its communication with the urethra. After ensuring that there is no distal obstruction to interfere with healing, we close the urethra.

Diverticula of the female urethra are covered in Chapter 90.

Paraphimosis, Balanitis, and Phimosis

Paraphimosis, or painful swelling of the foreskin distal to a phimotic ring, occurs if the foreskin remains retracted for a prolonged time. Swelling is sufficient to make reduction of the foreskin over the glans difficult. **In a very young child, paraphimosis is often seen after the foreskin has been traumatically reduced during an examination or sometimes by overzealous parental attempts at hygiene.** Traumatic, sudden reduction of a tight foreskin should be avoided in all ages and circumstances. To reduce a paraphimosis, gentle steady pressure must be applied to the foreskin to decrease the swelling; with a child, this is best accomplished in a quiet room by a parent squeezing it in the hand. Elastic wrap may be helpful in some cases. Putting an ice pack on the area for a short time before gentle compression is helpful as an analgesic. When the swelling has been reduced, the surgeon can push against the glans with the thumbs, pulling on the foreskin with the fingers. Because paraphimosis tends to recur, a dorsal slit at a minimum or a circumcision should be carried out as an elective procedure at a later date. An occasional patient presents with acute paraphimosis that has been present for many hours to days; this is typically seen in an adolescent who is reluctant to reveal the problem to his parents. In these cases, reduction may be impossible, and paraphi-

mosis should be dealt with by emergency dorsal slit or circumcision. Considerable postoperative edema is the rule in these cases.

Balanitis, or inflammation of the glans, can occur as a result of poor hygiene, from failure to retract and clean under the foreskin. The subsequent swelling makes cleaning more difficult, but the inflammation usually responds to local care and antibiotic ointment. Oral antibiotic therapy occasionally may be necessary. Balanoposthitis is a severe form of balanitis and occurs when the phimotic band is tight enough to retain inflammatory secretions, creating what amounts to a preputial cavity abscess. Occasionally, an emergent dorsal slit is required.

Phimosis, or the inability to retract the foreskin, can result from repeated episodes of balanitis. In older patients, balanitis may be a presenting sign of diabetes. In these cases, circumcision may be warranted.

Urethral Meatal Stenosis

A small urethral meatus in a newborn probably would not be called to a urologist's attention unless the stenosis is associated with other congenital deformities (e.g., hypospadias) or causes voiding difficulties or urinary tract infection (Allen and Summers, 1974). If the urethral meatus of a boy appears exceptionally narrow and there are associated symptoms, a meatotomy should be considered. For this decision to be made, voiding should be observed to note that the meatus opens as a full, forceful stream is passed. If the stream is narrow and excessively forceful, stenosis is probably present. The occluding skin is generally a thin layer that sometimes can be seen to pouch out, with the meatus opening at the dorsal lip as the child voids. **Meatal stenosis in a boy appears to be a consequence of circumcision that then allows subsequent ammoniacal meatitis.** If the child is seen with ammoniacal meatitis, we usually start meatal dilation with 0.05% clobetasol cream. Within a week, the process seems to abate. Anecdotally, the fusion of the ventral-meatal skin that causes meatal stenosis can be avoided. Parents must be counseled about the cause—that is, a wet diaper pressing for prolonged periods against the tip of the glans.

A ventral urethral meatotomy sometimes can be accomplished with the use of local anesthesia. In a young child, general anesthesia is the preferred approach, avoiding trauma to the child, the parents, and the urologist. It is important to insert the anesthetic needle into the skin fold from the underside so that the tip of the needle can be observed and controlled. If insertion is done from the outside, the needle passes through both layers of the fold, and a wheal cannot be raised because of leakage of the anesthetic solution. After the meatotomy, the edges of the cut seal together unless they are kept open. The tip of a meatal dilator is the best instrument for this purpose. The child's parents are instructed to separate the edges gently with the tip of the dilator three times a day for 7 to 10 days. The surgeon should observe the parents carry out this procedure. Pediatric meatal dilators (see later product reference) are available; however, the tip of an ophthalmic antibiotic tube also works well, and the antibiotic ointment can be used as the lubricant.

Meatal stenosis occurs in adults after inflammation, specific or nonspecific urethral infection, and trauma (especially in association with indwelling catheters, urethral instrumentation, or radical prostatectomy in some cases). It also may be the result of the failure of a previous hypospadias repair. To perform a ventral meatotomy in a normally developed penis in adolescents and adults, it is often necessary to place sutures to approximate the urethral mucosal edge to control bleeding. This step usually requires three sutures: one at the apex and one on either side. We have found a dilator made by Cook Urological (Spencer, IN; Catalog No. 073406, adult 6 to 34 French; No. 073403, pediatric 6 to 10 French) to be helpful in keeping the meatus open. In some cases, it may be necessary to perform a dorsal rather than a ventral meatotomy. This procedure can be accomplished as a Y-V-plasty after the excision of any scarred ridge of neourethra. Dorsal meatotomy, although effective in opening the meatus, often creates a cosmetically suboptimal shape of the meatus. In an adult, it is unusual for the meatal stenosis to

be an isolated finding. The stricture process usually involves the fossa navicularis to some extent as well.

Circumcision

Controversy continues regarding whether neonatal circumcision should or should not be performed (Poland, 1990; Schoen, 1990). Much attention has been focused on this issue, but despite this, many boys in the United States are circumcised. Ritual circumcision will continue; however, in ritual circumcision, it is not necessary to remove the skin but only to draw blood. **It is important not to circumcise any boy with a penile abnormality (e.g., hypospadias, chordee) that may require the foreskin during repair. Circumcision is indicated in a young boy who has had recurrent urinary tract infections thought to be associated with the redundant preputial skin.**

Most circumcisions performed just after birth are done with the Gomco clamp or one of the plastic disposable devices made for this purpose. Care should be taken to free the foreskin from the glans completely and to apply appropriate tension when the foreskin is pulled into the clamp. To prevent either a too generous or an inadequate circumcision, we find it useful to mark the foreskin carefully so that the correct level is ascertained. At our center, we perform neonatal circumcision with a penile block for anesthesia.

The most common complication is bleeding as a result of inadequate control with vascular compression. Application of an epinephrine-soaked sponge may help in controlling minimal venous bleeding. Infection can also occur and responds to local care. Any resulting skin separation should be repaired after the inflammation resolves. Minimal separation may be amenable to healing by secondary intention. Sometimes too much skin is removed, or the urethra is included in the clamp, resulting in a fistula. In many, if not most, cases in which excess skin is removed, closure can still be accomplished with aggressive frenuloplasty along with remaining skin closure by transposition of the remaining skin. If the entire penis is "scalped," it may be best managed with a split-thickness skin graft or with reapplication of the excised foreskin, after it is prepared properly as a graft. In complicated cases, burying the penis in the scrotum and repairing it at a later date may be prudent. **Monopolar electrocautery should be avoided in a neonatal circumcision because penile loss from the field distribution of the current can occur. The use of monopolar cautery with a Gomco or similar clamping device must be avoided because devastating loss of tissue can occur.**

A newborn who lost his penis because of a circumcision mishap should not be gender reassigned. Our experience with phallic construction includes many children and youths who had been converted to a female after a circumcision accident. As they passed through puberty, they realized that this sexual assignment was wrong. Most of these boys could undergo reconstruction in such a manner as to preserve reproductive function.

In adults, circumcision can be done with local anesthesia, by blocking the dorsal nerves at the base of the penis and circumferentially infiltrating the superficial layers of the penile base. In men and older boys, we favor a sleeve circumcision. With the foreskin in its retracted position, a marking pen outlines an incision, leaving a small preputial cuff. This mark should go straight across the base of the frenulum. This incision is made and carried through the dartos fascia to the superficial lamina of the Buck fascia. The foreskin is reduced, and a second incision is marked, following the outlines of the coronal margin and the V of the frenulum on the ventral side. The frenulum usually retracts into a V. In some cases, the frenulum can be lengthened by closing the edges of the V in a longitudinal orientation for a short length (frenuloplasty). If frenuloplasty is done, the proximal incision does not need to follow the V of the retracted frenulum because the ventral skin is straight. We make the skin incision and fulgurate bleeding vessels with bipolar cautery as the incision is deepened and the skin edge is mobilized. In older boys and men, the vessels are more substantial and not easily sealed by compression, no matter how vigorous. Circumcision clamps can be ineffective and are not recommended even

though larger sizes are available. After the sleeve of preputial skin has been removed, hemostasis is obtained, and the skin edges are reapproximated.

In younger boys, some surgeons may consider this sleeve procedure to be tedious and difficult. If this is the case, after the skin is marked, a dorsal slit is made through both layers of the prepuce back to the level of the corona. Following the marks, the two layers of the preputial skin are incised. Bleeders are controlled, and the skin edges are reapproximated.

Complications should be uncommon. Most patients develop some hyperesthesia of the glans, which resolves. A hematoma is probably the most common immediate complication. Some patients notice minor cosmetic imperfections that are functionally insignificant. One of the most distressing problems we see is a patient who complains that the surgeon has removed too much skin. To avoid this occurrence, a circumcision should be done precisely, and, whatever the procedure to be carried out, the incisions should first be marked with the skin lying undistorted on the shaft. Adults requesting circumcision must be carefully evaluated from a psychosexual standpoint because many of these patients who are the most persistent in requesting circumcision become the most dissatisfied after the surgery.

Circumcision has been shown in numerous studies to provide protection for men in areas where human immunodeficiency virus (HIV) is very prevalent (Auvert et al, 2005; Bailey et al, 2007; Gray et al, 2007). Circumcision has consistently been shown in well-conducted randomized controlled trials to reduce the risk of HIV acquisition in heterosexual African men by 50% to 60%. Similar prospective trials have not been performed in developed countries; however, retrospective data among heterosexual men in the United States showed a similar approximately 50% reduction in HIV prevalence among men with known exposure, suggesting the data may be extrapolated to this population. Additionally, male circumcision has been shown to reduce the risk for acquisition of herpes simplex virus type 2, human papillomavirus, genital ulcer disease, and some sexually transmitted bacterial infections (Tobian et al, 2014).

There is a biologic rationale for reduction in the spread of sexually transmitted infections, particularly HIV, with circumcision. Superficial Langerhans cells, CD4⁺ T cells, and CD8⁺ T cells are rich and less well protected by keratin on the inner aspect of the male foreskin and frenulum. When the foreskin is retracted during intercourse, this large and susceptible surface area is exposed allowing contact with HIV-infected secretions and subsequent risk for infection. Uncircumcised men have also been shown to have an increased frequency of genital ulcers and increased frequency of microtears during intercourse, both of which increase HIV transmission.

Despite the well-demonstrated benefit of circumcision in heterosexual men, the same benefit has not been shown for men who have sex with men (MSM). A large meta-analysis of more than 53,000 MSM did not demonstrate a statistically significant protection against HIV (Millett et al, 2008). Subgroup analysis demonstrated a trend toward reduced prevalence of HIV among MSM performing predominantly insertive rather than receptive anal intercourse, and others have corroborated these findings.

Failed Hypospadias Repair

In treating a patient in whom hypospadias repair has failed, it is important to obtain all available records to help determine what may have contributed to his complications. **A hypospadias repair may fail because of an inadequate correction of chordee or an inadequate urethra, with a stricture, fistula, or diverticulum (Winslow et al, 1986). It is often readily apparent from the records that not all aspects of the hypospadias deformity (i.e., ventrally displaced meatus, ventral chordee, and some expression of inadequacy of ventral tissue fusion) were addressed in the previous repairs.** Adults with urethral strictures are often seen who have had hypospadias surgery as children. Depending on the age of the patient and the preference of the treating urologist, a variety of different techniques may have been used to repair the original hypospadias. Many of these patients have persistent chordee and a

subcoronal meatus. Adults also have been seen who have had long-standing evidence of urethral fistula. In addition, some patients may have clinical findings not related to hypospadias that should have been recognized previously, especially when hypospadias is part of an overlying intersex problem. In the past, problems associated with previous failures were caused by errors in design, technique, or postoperative care (Devine et al, 1978). With more modern techniques available and with most hypospadias treated by surgeons with considerable experience, failures seem to be associated with perioperative infections or other factors that adversely affect wound healing. At the present time, complex hypospadias repair failures are encountered with much less frequency, and most that are encountered are in patients who had previous procedures more than 15 to 20 years ago. Complications in these patients resulted not from poorly designed surgery at the time but rather from the “state of the art” at the time.

Evaluation of a failed hypospadias repair includes retrograde urethrography, voiding cystourethrography, and cystoscopy. In an older patient, a reliable preoperative assessment of residual chordee can be made on the basis of the history and photographs taken at home. In younger patients, complete evaluation of more complex situations with use of anesthesia may be necessary.

In an adult patient, a detailed discussion must occur regarding the positive and negative aspects of the various approaches. Patients who were initially operated on before the late 1970s probably underwent either a graft or some form of repair using almost exclusively ventral tissue. Some of these patients still have the remnants of a dorsal hood or enough dorsal skin for a dorsal transverse penile skin island type of reconstruction to be performed.

We believe that surgical correction of complex cases requires an aggressive approach by the surgeon (Secrest et al, 1993). However, with the advent and very common usage of the tubed incised plate repair, initially described by Snodgrass (1999), the nature of failures is different, and the approaches also are remarkably different. Based on our observations, the number of failed surgeries is less, the nature of graft salvage techniques is remarkably different, and the method of addressing residual curvature is different. It is possible to reincise the “urethral plate” and tubularize it if the plate is not scarred and possible to graft the plate dorsally if it is; if the tissues are badly scarred, many surgeons revert to staged reconstruction (Snodgrass et al, 2009). The use of flaps has a place in corrective procedures, and the excision of scarred tissues causing residual curvature likewise has its place. However, plication or corporoplasty techniques for correction of residual curvature have, for the most part, become the standard of care. Graft techniques for correction of curvature are used but with far less frequency than in years past.

Residual Genital Abnormality in Patients with Closed or Diverted Exstrophy

Residual genital defects in men who have had exstrophy repaired as children can cause functional, aesthetic, and psychologic problems. The effects of these problems are compounded in men who have undergone urinary diversion and who must wear stomal appliances, although with the improvement of continent diversions, this is less of a factor. Successful reconstruction is possible except in the most severe forms of bladder exstrophy or cloacal exstrophy—when the penis or the halves of the bifid penis are truly inadequate. Even then, if normal testes are present, the success of newer techniques of phallic construction (see subsequent discussion) should lend support to considering the option of raising such a child as a boy, possibly preserving his reproductive potential through puberty. In these very difficult cases, we think that the parents must be presented with both options, gender reassignment versus eventual phalloplasty. Remarkable progress has been made in the treatment of difficult cases (Johnston, 1975; Hendren, 1979; Jeffs, 1979; Snyder, 1990; Perovic et al, 1992; Gearhart et al, 1994; Mitchell and Bagli, 1996) and in techniques of primary closure. However, many patients need further genital surgery because they

experience the hypertrophic growth spurt of the penis associated with puberty.

The goals of reconstructive surgery in male patients with exstrophy or epispadias are to produce a dangling penis with erectile bodies of satisfactory length and shape to allow sexual function and to construct a urethra that serves as a conduit for the passage of urine and ejaculate. However, experience has shown that in a patient with a diverted exstrophy and only a bladder remnant, construction of a urethra that is essentially defunctionalized is difficult. These urethras all eventually seem to fibrose and stenose. The bladder neck remnant becomes a cyst that is often colonized. Bouts of virulent epididymitis or the formation of what is really a bladder neck remnant abscess begin to occur. We have seen two patients who developed carcinoma of the prostate in a bladder neck remnant. The diagnosis in these patients was difficult, and the resultant surgery was even more difficult. Neither patient did well from the standpoint of treatment of the carcinoma. Both were seen before the aggressive use and better understanding of prostate-specific antigen.

Many patients who have undergone surgery as children do not present for correction of inadequacies of the external genitalia until after they have completed puberty and realize that their situation has not improved and is not likely to improve. Some have been in sexual situations and have encountered problems. We employ a systematic approach to accomplishing the reconstruction necessary to correct the anatomic defects in these patients (Devine et al, 1980; Winslow et al, 1988). Surgery is undertaken in a sequential fashion beginning with the simplest procedure that would achieve the desired functional result.

Lower abdominal wall scarring can be corrected or defects can be closed by fashioning peripenile flaps that are shaped like a W. In many patients, there may be wide diastasis recti that is really a ventral hernia. Anchoring of meshes or Gore-Tex can be difficult, and we have resorted to a fibular bone microvascular free transfer in several cases to reconstruct the continuity of the pubis, allowing effective closure of the abdominal hernia.

With more effective contemporary primary closure techniques, the adult reconstructive surgeon's place is primarily in the correction of hernia, or in the patient who has an inadequate penis either due to deformity, scarring, or improper gender reassignment.

TRAUMA TO THE GENITALIA

This topic is primarily covered in Chapter 101, but an additional description is included in the electronic version of this chapter. Please see the Expert Consult website for this section and Figure 40-15.

URETHRAL STRICTURE DISEASE

The term *urethral stricture* refers to anterior urethral disease, or a scarring process involving the urethral epithelium or spongy erectile tissue of the corpus spongiosum (spongiofibrosis) (Fig. 40-16). The spongy erectile tissue of the corpus spongiosum underlies the urethral epithelium, and the scarring process extends through the tissues of the corpus spongiosum in some cases and into adjacent tissues. **Contraction of this scar reduces the urethral lumen.** For example, if a normal urethra measures 30 Fr, its diameter is 10 mm, and the area of the lumen is approximately 78 mm². If scarring has resulted in a urethra that measures 15 Fr, the lumen is only 55 mm², or 29% reduced. It is evident that scar contraction caused by anterior urethral stricture disease can be asymptomatic for a while, but because the lumen is further reduced, it can be associated with marked voiding symptoms.

In contrast, posterior urethral “strictures” are not included in the common definition of urethral stricture. Posterior urethral stricture is an obliterative process in the posterior urethra that has resulted in fibrosis and is generally the effect of distraction in that area caused by either trauma or radical prostatectomy. Although the distraction defect can be lengthy in some cases, the

Figure 40-15. Technique of microscopic replantation after amputation of the penis. **A**, The typical appearance of a penile amputation injury. **B**, The urethra, corpora cavernosa, and dorsal neurovascular structures are exposed and minimally debrided. **C**, A two-layer spatulated urethral anastomosis is completed. Microvascular coaptation of the dorsal vein, dorsal artery, and dorsal nerves is accomplished. **D**, Coverage is accomplished with the native skin. If the patient is circumcised, the sleeve of skin between the amputation injury and the old circumcision scar should not be discarded. Should chronic edema develop, revision can be accomplished at a later date. Diversion is by way of a suprapubic cystostomy tube. A stent is inserted in the reconstructed urethra. (From Jordan GH, Gilbert DA. Management of amputation injuries of the male genitalia. *Urol Clin North Am* 1989;16:359–67.)

Penetrating Trauma to the Penis

Penetrating injuries of the penis can involve the urethra, the corporeal bodies, or both. Our choice in managing the acute injury is exploration and attempted immediate anatomic repair, perhaps placing a suprapubic tube should extensive urethral reconstruction be required. With bullet trauma, the velocity and the construction of the projectile are important factors. Small, “slow”-bullet injuries of the urethra can be successfully reconstructed primarily; however, larger, high-velocity wounds may require diversion and delayed reconstruction. Some projectiles are designed to fragment and, even if “low velocity,” can cause considerable adjacent tissue damage. Later reconstruction is directed at urethral stricture (if it occurs after the initial injury), or there is curvature of the penis secondary to damage of the corporeal bodies, or both are present. Fistulae that result from penetrating trauma to the penis are usually treatable by primary closure with interposition of superficial tissue layers between the urethra and the skin. Large fistulae may require more

complex tissue transfer and, in many ways, become more of a problem of urethral reconstruction as for stricture. The principles are discussed elsewhere in the chapter. Because of recent military actions, in which injury is due to blasts with shrapnel and high-velocity nonfragmenting projectiles, thinking on mechanisms surrounding penetrating trauma has been redefined. For example, high-velocity projectiles can truly penetrate peripheral structures with little cavitation effect, not the effect previously noted with wounds to the abdomen and chest.

Amputation of the Penis

Amputation is the ultimate penetrating penile injury. If the patient presents acutely with the amputated distal part of his penis, microvascular replantation is the favored approach (Fig. 40-15). If there is no microvascular surgeon at the center where the patient presents, he should be transferred. The amputated portion of the penis should be cleaned, wrapped in a sponge soaked in sterile saline, and placed in a sterile zipper-sealed plastic bag. The amputated penis is kept in ice slush, and replantation can be accomplished 18 to 24 hours after amputation. Often, the amputation is self-inflicted, usually during an acute psychotic break. This situation should not preclude replantation unless the patient adamantly refuses such treatment. Even then, with a court order or the agreement of two or more surgeons, replantation may be undertaken. Current legal opinion regarding a patient’s right of refusal is unhelpful in clarifying circumstances in which a patient refuses treatment but may not really be capable of true informed consent. Applying for a court order may be the safest method for obtaining consent. The patient’s condition or other circumstances may prevent his transfer for microvascular replantation. If so, replantation by the technique described by McRoberts and colleagues (1968) should be carried out. This and other series show that a high degree of success can be expected after replantation without microvascular reanastomosis (Chapple et al, 2004; Morey et al, 2004).

If the patient presents with the distal part having been disposed, or otherwise unavailable, the wound should be closed. The penis has often been stretched out during the amputation, and an excess of skin has been removed, leaving a length of intact but denuded shaft structures proximal to the amputation wound. We close the corporeal bodies with 4-0 or 5-0 polydioxanone suture, widely spatulate the urethral meatus, and immediately cover the penile shaft with a split-thickness skin graft. Other surgeons bury the shaft beneath the skin of the scrotum. In some of these patients, primary grafting of the stump allows a functional penis. However, many patients require phallic construction or penile reconstruction later.

Many sophisticated techniques for reconstruction of the traumatized penis are available. Forearm flaps have become the mainstay of penile reconstructive procedures (see subsequent discussion). The initial stage of reconstruction of the amputated penis consists of mobilization of the penile and urethral stumps.

Degloving Injuries of the Penis

Degloving injuries occur when the skin of the penis or scrotum is trapped and stripped from the deeper structures, exposing the uninjured corpora cavernosa and the testes. The tear is deep to the elastic dartos fascia. Bleeding is usually not a problem because there are not many large vessels in this space. However, the appearance of the “bare” testes and penile shaft is impressive.

When the patient presents, the wounds should be dressed in sterile saline-soaked bandages. A delay of approximately 24 hours is sufficient to define the extent of the damage. Most degloving injuries can be managed acutely with immediate reconstruction by the application of split-thickness skin grafts. The shaft is covered with a sheet graft of split-thickness skin. The testes are sutured together in the midline, fixed in their anatomic correct position, and covered with a meshed split-thickness skin graft. In the acute trauma situation, we have had good success with acute grafting and have not required temporary skin substitutes to prepare the graft bed. The parietal tunica vaginalis is opened, and the graft is placed

directly on the testes. After take of this graft, the meshing gives the appearance of rugae. With time, the effect of gravity on the testes causes the reconstructed scrotum to become pendulous and sometimes even redundant. In this repair, split-thickness skin grafts are more successful than full-thickness skin grafts because the host bed is suboptimal after a degloving injury. Although split-thickness grafts cannot be employed for single-stage urethroplasty because of contraction, contraction has not been a problem with such grafts applied to the penile shaft or testes. Adequate shaft sensation is achieved by means of the deep structures beneath the graft. Should the testis be avulsed as part of the injury, replantation is usually not an option because the process of stretching of the vessels before breaking leads to an unpredictable intimal injury.

Some surgeons bury the shaft of the penis in a subcutaneous tunnel on the abdomen and bury the testes in subcutaneous thigh pouches. McDougal (1983) described a technique to mobilize the buried testes with the overlying thigh skin, combining scrotal reconstruction with testicular replacement; this is a good way of transposing the testes and overlying tissues to an anatomically correct location. When we have managed patients who have been previously treated acutely with the placement of the testes and penis in subcutaneous tunnels, we have mobilized the testes and the penile shaft from their tunnels and immediately applied grafts of split-thickness skin, as already discussed (Morey et al, 2004).

Genital Burns

The ability to reconstruct the damage caused by genital burns often depends on how well the normal structures have been maintained after the acute injury. Careful debridement is the rule in acute management of genital burns. Corporeal tissue cannot be replaced with transferred tissue. The physiologic functions of genital tissues cannot be accurately duplicated. The unique vascularity of genital tissue allows less aggressive rather than more aggressive debridement.

Devastating urethral injuries occur with many burns. Reconstruction of the urethra depends on the nature of the injuries. When the urethra has been nearly obliterated, there usually is insufficient uninvolved, nonhirsute local genital tissue that can be transferred for urethral reconstruction. Vascularized tissue must be imported to support reconstruction of the urethra with graft techniques. In many patients, the penis has become incarcerated in contracted scar tissue after the acute injury is healed. Successful transposition of a gracilis musculocutaneous flap introduces compliant vascular tissue and skin into the area, allowing release of the penile shaft. Subsequently, the penile shaft can be covered with a split-thickness skin graft. In some patients, the genital scarring is so severe that microvascular transfer of a free flap is necessary to replace the penile shaft.

For many patients, reconstruction requires numerous stages. In several of our patients, the urethra was obliterated literally from the entry of the membranous urethra into the bulbospongiosus to the tip of the penis. A perineal urethrostomy was required while transfer of vascular tissues to the area of the perineum and penis was accomplished. When these tissues are in place, subsequent reconstruction of the urethra can be undertaken with meshed split-thickness skin grafts or buccal mucosal grafts. For coverage of large perineal or groin defects, the posterior thigh flap offers excellent bulky, sensate tissue.

Radiation Trauma

Radiation trauma to the penis occurs in two subsets of patients: patients in whom radiation has been used therapeutically for a

lesion on the penis and patients in whom radiation to the pelvis has caused chronic lymphedema. Therapeutic radiation can produce chronic suppurative gangrene. In most cases, these lesions are not amenable to reconstruction and are best managed by partial penectomy and later reconstruction, when the patient is proved to be cancer free. Also, we have treated several patients who developed tissue atrophy and further fibrosis after radiation therapy for Peyronie disease. Delivered at near-tumoricidal doses, this radiation made dermal graft repair much more difficult.

In patients who have had pelvic irradiation, the genitalia usually have one or more of the following: lymphedema, cellulitis, weeping of fluid, or lymphangiectasia. If cellulitis is part of the problem, prolonged treatment (i.e., for months) should be considered before reconstruction. We have had several patients with recurrent cellulitis who had prolonged antibiotic therapy (we use ciprofloxacin); not only did their cellulitis become quiescent, but also the lymphedema resolved significantly.

The genitalia of patients with lymphedema can be readily reconstructed. Lymphedema of the penis involves the tissues of the dartos fascia and the dermal layer of the skin. In the penis, the lymphedematous tissue can be excised by removing the dartos fascia and skin, dissecting in the layer immediately superficial to Buck fascia. In the scrotum, Colles fascia–tunica dartos and skin of the scrotum must be removed. When the lymphedematous tissue has been excised, the testes are free, and, as in a degloving injury, they must be fixed in the midline in an anatomically correct position. The scrotal skin peripheral to the edema is often normal and can be advanced to cover the testes. The shaft of the penis should be covered with a split-thickness skin graft. If the scrotum cannot be closed, a meshed split-thickness skin graft is used to cover the testes, as described previously. Grafts provide optimal reconstruction in these patients. These patients commonly have hydroceles; the parietal tunica vaginalis must be excised, and grafting can be done directly onto the visceral tunica vaginalis of the testes. If there are hydroceles, the process often is “systemic” and not local. In these cases, reconstruction using the lateral scrotal skin is seldom effective. In contrast to a full-thickness skin graft, split-thickness skin carries little of the reticular dermis and few of the lymphatic channels. Reaccumulation of lymphedema occurs within a full-thickness skin graft and can recur in a thick split-thickness graft. Local skin flaps should be avoided as previously mentioned. They often reaccumulate lymphedema when they have been transposed to the area of the genitalia. As previously noted, grafts do not develop sensation. However, good sensation usually develops, derived from the deep structures. The glans almost never accumulates disabling edema, and the sensation of the glans remains intact because the lymphedematous tissue has been excised in the plane superficial to Buck fascia, sparing the dorsal nerves of the penis. In many cases of genital lymphedema, the posterior scrotum and the lateral scrotal wall are spared from the edematous process; in these cases, the bulk of the scrotum is excised, and closure is accomplished with use of the posterior and lateral scrotum. If the edematous process also involves the lower extremities, it is best to reconstruct the scrotum with a graft as opposed to the local tissues.

Direct radiation to the penis can cause urethral injury. However, it is unusual for the urethra to be injured without damage to adjacent structures. Often, because of the vascularity of the corpus spongiosum, minimal debridement can be accomplished, leaving the patient with a fistula that can be reconstructed at a later date. The success of such reconstruction depends on the damage that the radiation has done to the adjacent structures.

KEY POINTS: TRAUMA TO THE GENITALIA

- Penetrating injuries to the penis can involve the urethra, the corporeal bodies, or both.
- With regard to bullet injuries of the urethra, the velocity of the projectile must be considered. However, recent military actions have shown that high-speed projectiles can pass through superficial structures with relatively little cavitation effect and less propagation of energy to the adjacent tissues.
- If the patient presents acutely with the amputated distal part of his penis, microvascular replantation is the favored approach. If the patient's condition or other circumstances prevent his transfer for microvascular replantation, replantation by the technique described by McRoberts should be carried out and can yield excellent results.
- Degloving injuries to the penis occur when the penis or scrotal skin is trapped and stripped from the deeper structures. Bleeding is usually not a problem. The tissues must be allowed to demarcate; acute reconstruction with grafts can be done.
- The damage caused by genital burns depends on how well the normal structures have been maintained after the acute injury. The unique vascular qualities of the penis allow careful repeated debridement as opposed to aggressive debridement.
- Radiation trauma to the penis occurs in two potential subsets: patients in whom radiation has been used therapeutically for a lesion on the penis and patients in whom radiation to the pelvis has caused chronic lymphedema. A patient with genital lymphedema can readily undergo reconstruction with either a split-thickness skin graft or, in select cases, the lateral margins and the posterior margins of the scrotum.

KEY POINTS: SELECTED PROCESSES

- Urethral hemangioma is a rare condition that is usually persistent. It can present a significant challenge to the surgeon. All reported cases of urethral hemangioma have been benign, and management depends on the size and location of the lesion.
- Reactive arthritis is characterized by a classic triad of arthritis, conjunctivitis, and urethritis. Urethral involvement is usually mild, self-limited, and a minor portion of the disease.
- LS previously was referred to as balanitis xerotica obliterans. Diagnosis is made through biopsy. LS is thought to be possibly premalignant for the development of squamous cell carcinoma of the glans. It is the most common cause of meatal stenosis. Management of patients with LS-related stricture is complex, and results to date are suboptimal. The management is determined by the desire of the patient and the need for functional reconstruction.
- Amyloidosis is a rare disease of the urethra and should be considered in the evaluation of any patient with a urethral mass. Patients present with hematuria, dysuria, or urethral obstruction.
- A urethrocutaneous fistula is a tract lined with epithelium that leads from the urethra to the skin. It may be a complication of urethral surgery or develop secondary to periurethral infection associated with inflammatory strictures or treatment of a urethral growth. Treatment of the urethral fistula must be directed not only to the defect but also to the underlying process that led to its development.
- A congenital urethral diverticulum is a transitional cell epithelium-lined pouch that is the result of either a distention of a segment of the urethra or the attachment of a structure to the urethra by a narrow neck. In male patients, "congenital" anterior urethral diverticulum may result from incomplete development of the urethra or possibly may be the result of straddle trauma that led to an intracorporeal spongiosal hematoma. Congenital diverticulum in the prostatic urethra is a remnant of the müllerian duct.
- Paraphimosis is a painful swelling of the foreskin distal to a phimotic ring. It occurs when the foreskin has been retracted and not reduced. Edema forms in the distal skin.
- Urethral meatal stenosis in a young boy appears to be a consequence of circumcision. The circumcision allows the development of ammoniacal meatitis, which can heal with a membrane across the ventral portion of the meatus. Controversy continues regarding whether neonatal circumcision should or should not be performed. If it is going to be performed, the circumcision needs to be adequate. The most common complication of neonatal circumcision, in our opinion, is when it is inadequately done.
- A patient with failed hypospadias repair can be complex. Many are victims of the technology of the time when they had their initial reconstruction. All patients with urethral involvement should be evaluated as if they have urethral stricture disease.
- Advanced techniques for the reconstruction of the exstrophy-epispadias complex have led to much better functional results and less need for secondary exstrophy reconstruction. Secondary exstrophy reconstruction is aimed at the area of the escutcheon, the dorsal base of the penis, the penile shaft, the urethra, and the penoscrotal junction.

actual process involving the tissues of the urethra is usually confined. By consensus of the World Health Organization conference, the term *stricture* is limited to the anterior urethra. Distraction defects are processes of the membranous urethra associated with pelvic fracture. Other narrowings of the posterior urethra are termed *urethral contractures* or *stenoses* (Bhargava et al, 2004).

Urethral Anatomy

Although urethral anatomy is described in the earlier section on anatomy, it is useful to re-emphasize key anatomic points. The **bulbous urethra is eccentrically placed in relation to the corpus spongiosum and is much closer to the dorsum of the penile structures** (see Fig. 40-6). As one moves distally, the pendulous or penile urethra becomes more centrally placed within the corpus spongiosum.

The genital skin has a dual (proximal and distal) and bilateral blood supply, forming a fasciocutaneous system (see Fig. 40-10). The corpus spongiosum receives blood from the common penile artery, the terminal branch of the internal pudendal artery (see Fig. 40-12). The corpus spongiosum also has a dual blood supply—a proximal blood supply and a retrograde blood supply through the dorsal arteries as they arborize in the glans penis.

Etiology

Any process that injures the urethral epithelium or the underlying corpus spongiosum to the point that healing results in a scar can cause an anterior urethral stricture. Most urethral strictures are the result of trauma (usually straddle trauma). This trauma to the urethra often goes unrecognized until the patient presents with voiding symptoms resulting from the obstruction of the stricture or scar. In most cases of straddle trauma, reconstruction of the bulbar urethral injury is possible (Park and McAninch, 2004). Iatrogenic trauma to the urethra still exists, but with the development of small endoscopes and the limitation of indications for cystoscopy in boys, we see fewer iatrogenic strictures today than in the past. The place of idiopathic urethrorrhagia with regard to strictures in children is unclear; some question whether it may be a cause of strictures in young boys regardless of whether the child underwent an endoscopic procedure (Rourke et al, 2003). No specific inciting factor has been identified as causing idiopathic urethrorrhagia. Histologic results from a patient of ours with resolving urethrorrhagia showed portions of tissues covered in part by squamous epithelium; other parts were covered by transitional epithelium; there were several areas of denuded epithelium with acute hemorrhage and neutrophilic infiltration; a few foci of microcalcification were shown; several mucus glands were found within the submucosal connective tissue as well as a few collections of amorphous material, likely mucin. These areas stained negatively with a special stain for amyloid. There was no evidence of viral cytopathic effect or malignancy. We did not see evidence of bacterial infection or viral inclusions. However, we have seen an increase in strictures associated with LS, and those strictures clearly behave much more like inflammatory strictures than traumatically induced isolated scars. Finally, posterior urethral injuries, traumatic by definition, result in obliterative or near-obliterative defects that are associated with extensive fibrosis interposed between the distracted ends of the urethra.

Inflammatory strictures associated with gonorrhea were the most commonly seen in the past and are less common now. With the advent of prompt and effective antibiotic treatment, gonococcal urethritis progresses less often to gonococcal urethral strictures. The place of *Chlamydia* and *Ureaplasma urealyticum* (i.e., nonspecific urethritis) in the development of anterior urethral strictures is unclear. No clear association between nonspecific urethritis and the development of anterior urethral stricture has been established.

As mentioned earlier, there is a definite association between the development of an inflammatory stricture and LS. LS usually begins with inflammation of the glans and inevitably causes meatal stenosis, if not a true stricture of the fossa navicularis. The cause of this distal penile skin and urethral inflammation is unknown. Some evidence suggests that the progression of the stricture eventually to involve the anterior urethra extensively may be due to high-pressure voiding that causes intravasation of urine into the glands of Littre, inflammation of these glands, and, perhaps, microabscesses and deep spongiobiosis. Whether the urethral changes and eventual fibrosis are also related to bacterial injury has not been well defined. Although the use of antibiotics seems to limit obstructive voiding

Figure 40-16. The anatomy of anterior urethral strictures includes, in most cases, underlying spongiofibrosis. A, Mucosal fold. B, Iris constriction. C, Full-thickness involvement with minimal fibrosis in the spongy tissue. D, Full-thickness spongiofibrosis. E, Inflammation and fibrosis involving tissues outside the corpus spongiosum. F, Complex stricture complicated by a fistula. This can proceed to the formation of an abscess, or the fistula may open to the skin or the rectum. (From Jordan GH. Management of anterior urethral stricture disease. *Probl Urol* 1987;1:199–225.)

symptoms in these patients, to our knowledge the literature does not show resolution of the stricture process with the use of antibiotics.

The entity known as a congenital stricture is difficult to understand. In embryologic development, if a stricture is found at a natural place where a fusion of structures occurs (i.e., the posterior and anterior urethra), a congenital stricture might be a reasonable assumption. However, the term *congenital stricture* is used by some authors to define a stricture for which there is no identifiable cause. We propose that it is reasonable to define a stricture as congenital only if it is not an inflammatory stricture, it is a short-length stricture, and it is not associated with a history of or potential for urethral trauma. These criteria limit the term *congenital stricture* to strictures of the anterior urethra found in infants before they attempt erect ambulation. So defined, congenital strictures are the rarest encountered.

Diagnosis and Evaluation

Patients who have urethral strictures most often present with obstructive voiding symptoms or urinary tract infections such as prostatitis and epididymitis. Some patients also present with urinary retention. However, on close inquiry, most of these patients are found to have tolerated notable voiding obstructive symptoms for a long time before progressing to complete obstruction.

When a patient cannot void, an attempt commonly is made to pass a urethral catheter. If the catheter does not pass, the nature of

the obstruction is determined by dynamic retrograde urethrography. Most cases are managed with acute dilation, and there are many instances in which this is not the best course for the patient. When there is doubt, we determine the nature of the stricture when possible, and selectively place a suprapubic cystostomy catheter to treat the acute situation and allow time for a more appropriate treatment plan to be devised. The practice of blind passage of filiforms and blind dilation without knowledge of the anatomy of the urethral stricture is condemned. Although detailed imaging is not always available, flexible endoscopy is almost universally available in the United States. The stricture can be visualized, and guidewire placement under direct vision can be attempted.

For an appropriate treatment plan to be devised, it is important to determine the location, length, depth, and density of the stricture (spongiofibrosis). The length and location of the stricture can be determined with radiography, urethroscopy, and ultrasonography. The depth and density of the scar in the spongy tissue can be deduced from the physical examination, the appearance of the urethra in contrast-enhanced studies, and the amount of elasticity noted on urethroscopy. The depth and density of fibrosis are difficult to determine objectively. The absolute length of spongiofibrosis may not be evident on ultrasound evaluation. Ultrasound examination can augment contrast-enhanced studies and is accurate in determining the length of narrow-caliber annularity (Morey and McAninch, 1996b). Contrast studies of the urethra are best carried out by or under the direct supervision of the surgeon responsible for treatment of the patient.

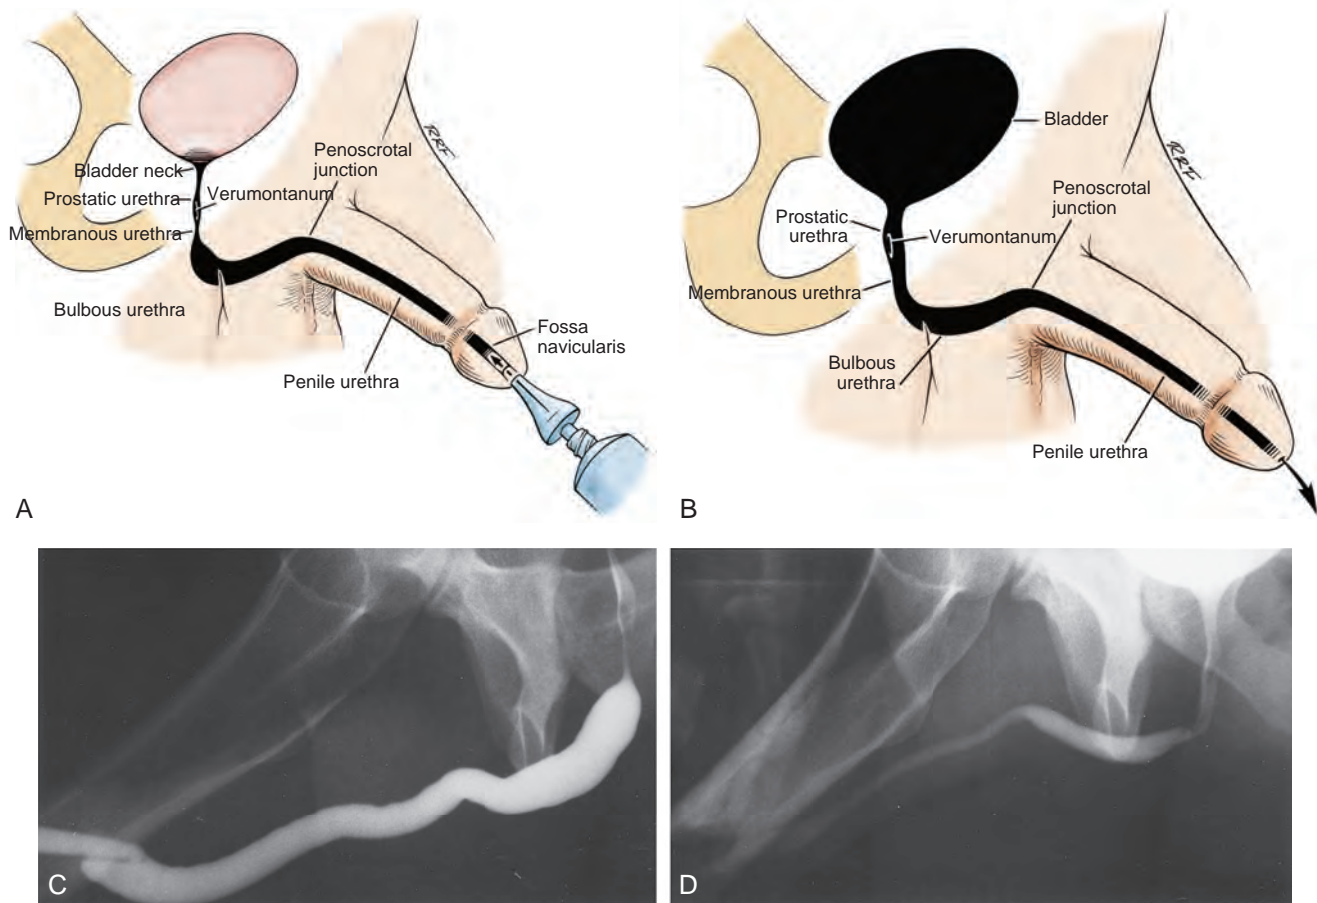

Figure 40-17. A, Representation of a dynamic retrograde urethrogram with the criteria of McCallum illustrated. B, Representation of a dynamic voiding urethrogram with the criteria of McCallum illustrated. C, Normal retrograde urethrogram. D, Normal voiding urethrogram. (A and B, Modified from McCallum RW. The adult male urethra. *Radiol Clin North Am* 1979;17:227-44.)

McCallum and Colapinto (1979a, 1979b) described the use of dynamic radiographic studies and emphasized the need for these studies to be dynamic as opposed to static (Fig. 40-17). At our center, imaging includes dynamic studies that are performed during retrograde injection of contrast material and while the patient is voiding. Even with gentle technique, extravasation during retrograde urethrography is possible in patients in whom the urethra is markedly inflamed. For this reason, contrast studies should be carried out with contrast material that is suitable for intravenous injection and used either directly from the bottle or diluted according to the manufacturer's guidelines. Contrast materials that have been thickened with lubricating jelly or anesthetic gels can be a source of problems and offer little with regard to enhancement of radiographic studies, and they do not make the studies more comfortable. Real-time ultrasound evaluation of the urethra after it has been filled with a lubricating jelly or saline has been described by Morey and McAninch (1996a, 1996b). However, it is a misconception that ultrasonography always directly visualizes the spongiositis. Morey and McAninch (1996a, 1996b) believed that ultrasonography of the bulbous urethra possibly more accurately determines the length of the stricture, which could be important in considering an anastomotic repair. If the patient is not in steep lateral oblique position for retrograde urethrography, the length of the stricture will be underestimated. Finally, during contrast-enhanced urethrography, more than one projection may be necessary to visualize the stricture. Magnetic resonance imaging (MRI) is also being explored as an adjunct to the evaluation of urethral stricture and pelvic fracture urethral injuries (PFUIs). In

our experience, the use of MRI for routine strictures or pelvic fracture urethral distraction defects is not routinely beneficial. In the case of urethral tumors, we have found MRI to be invaluable. The experience of others is commensurate with ours (Pavlica et al, 2003). In a pelvic fracture urethral distraction defect, the alignment of the two urethral ends can be defined clearly.

Endoscopic examination may be necessary after contrast studies. The flexible cystoscope has simplified this evaluation, and when local anesthesia is used, there is little discomfort associated with it. The scope can be passed to the stricture, and it often is unnecessary to pass it beyond that level. In addition, it is not always necessary, and usually not beneficial, to dilate the stricture at the time of the initial endoscopic evaluation. Pediatric endoscopic equipment has proved to be extremely valuable for examination of the urethra proximal to a narrow-caliber area without the need to dilate the narrowest area. In a patient who cannot void and has a suprapubic tube, combined contrast studies with endoscopy are helpful in defining the stricture anatomy (Fig. 40-18).

It is imperative to evaluate the urethra completely proximal and distal to the stricture with endoscopy and bougienage during surgery to ensure that all the involved urethra is included in the reconstruction. Although hydraulic pressure generated by voiding may keep segments proximal to the stricture patent, unless these segments are included in the repair, they are at risk for contraction after obstruction of the narrow-caliber segment is relieved with reconstruction. For this reason, any abnormal areas of the urethra that are proximal to a narrow-caliber segment of the stricture must be treated with suspicion. If the lumen does not appear to

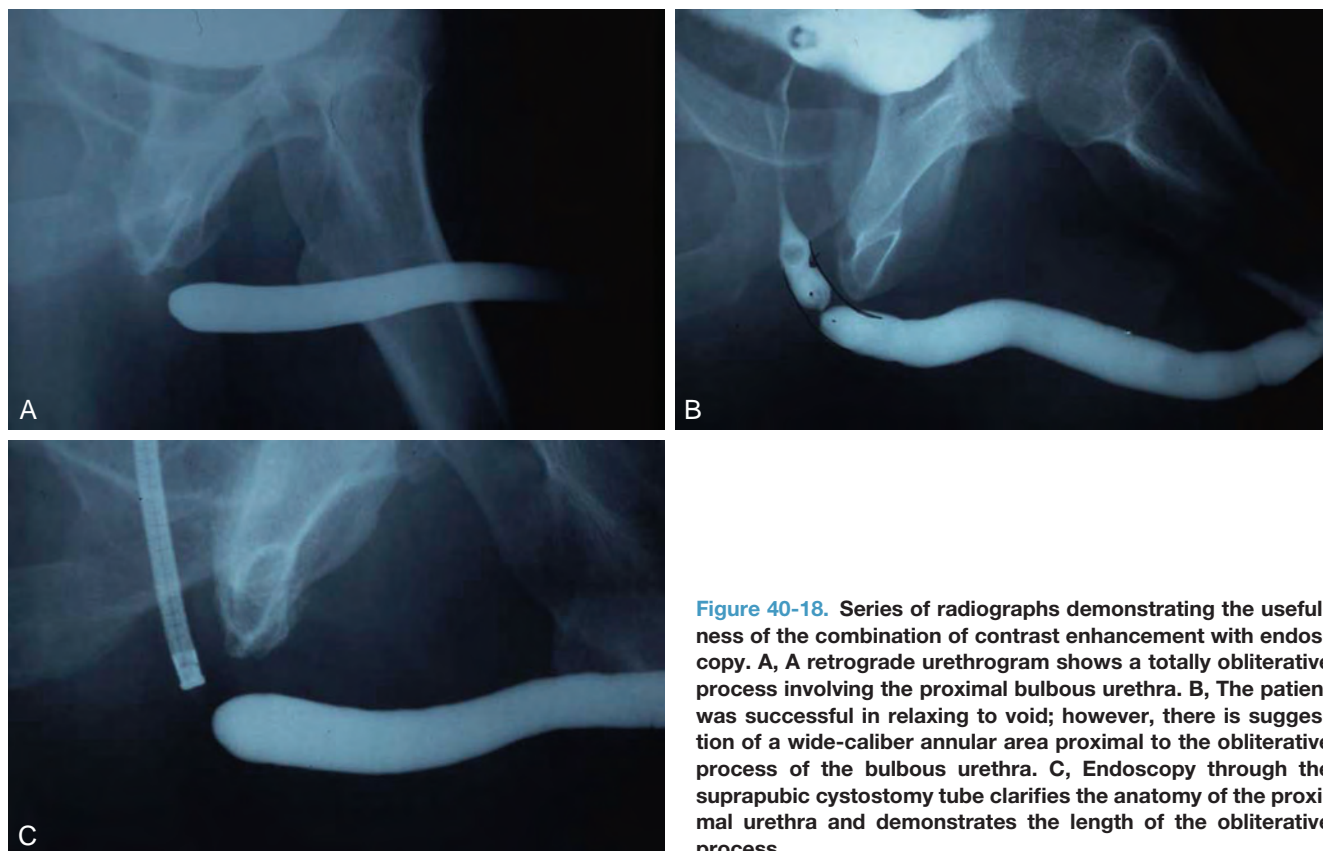

Figure 40-18. Series of radiographs demonstrating the usefulness of the combination of contrast enhancement with endoscopy. **A**, A retrograde urethrogram shows a totally obliterative process involving the proximal bulbous urethra. **B**, The patient was successful in relaxing to void; however, there is suggestion of a wide-caliber annular area proximal to the obliterative process of the bulbous urethra. **C**, Endoscopy through the suprapubic cystostomy tube clarifies the anatomy of the proximal urethra and demonstrates the length of the obliterative process.

demonstrate evidence of diminished compliance, we presume that area to be uninvolved in active stricture disease. However, coning down of the urethra suggests its involvement in the scar.

In some patients, the urethra proximal to a narrow area may remain confusing with regard to its potential for continued constriction after reconstruction. In select patients, we have found it useful to place a suprapubic tube to defunctionalize the urethra. After 6 to 8 weeks, if there is to be constriction of an area that was hydrodilated with voiding, the tendency for that constriction to occur should become apparent.

Treatment

Although the treatment of urethral stricture disease dates to the foundations of urology, significant progress made during the last 50 years allows many of the most complex strictures to be reliably reconstructed in one stage. In the past, a concept known as the reconstructive ladder was used as a treatment guideline for urethral strictures. That concept was based on the principle that the simplest procedure should always be attempted first, and sometimes repeated after failure, before moving on to more complex approaches. This approach is considered archaic in modern urethral reconstruction.

The patient and the physician must have a good understanding of the goal of treatment before the treatment choice is made. Treatment options should be discussed with the patient, with care taken to emphasize the anticipated outcome with regard to potential cure. Some patients may prefer stricture management and choose to have periodic dilations in the office, at home, or in the hospital rather than undergo technically detailed open surgery. Others may have cure as a goal and choose surgical management. Many surgical procedures today have short-term and mid-term results approaching long-term success rates of more than 90% to 95% for many strictures.

KEY POINTS: URETHRAL STRICTURE

- The term *urethral stricture* refers to anterior urethral disease and is a scarring process that involves the epithelium and the spongy erectile tissue of the corpus spongiosum. Contraction of the scar reduces the urethral lumen. Posterior urethral strictures are more correctly referred to as PFUIs; strictures of the prostatic urethra or bladder neck are properly referred to as contractures or stenoses.
- The anterior urethra is invested by the corpus spongiosum, and as it proceeds proximally it is eccentrically placed in relation to the corpus spongiosum. The genital skin has a dual and bilateral blood supply, forming a fasciocutaneous vascular system. The vascularity of the corpus spongiosum is based on the common penile artery.
- In general, most anterior urethral strictures are the result of trauma. Inflammatory strictures associated with gonorrhea are rarely seen; however, strictures associated with LS have behavior similar to inflammatory strictures.
- Patients who have urethral strictures most often present with obstructive voiding symptoms or urinary tract infections such as prostatitis and epididymitis. Patients who present with urinary retention, on close inquiry, have tolerated notable voiding obstructive symptoms for a long time.
- For an appropriate treatment plan to be devised, it is important to determine the length, location, depth, and density of the spongiofibrosis. This determination can be done with a combination of contrast-enhanced studies, endoscopy, and selective ultrasonography. It is imperative to evaluate the urethra completely proximal and distal to the stricture with endoscopy. A pediatric cystoscope is useful.

Dilation

Urethral dilation is the oldest and simplest treatment of urethral stricture disease, and for a patient with an epithelial stricture without spongiofibrosis, it may be curative. **The goal of this treatment, a concept that is frequently forgotten, is to stretch the scar without producing more scarring.** If bleeding occurs during dilation, the stricture has been torn rather than stretched, possibly further injuring the involved area.

The least traumatic method to stretch the urethra is to use soft techniques over multiple treatment sessions. We believe that the safest method of urethral dilation currently available involves the use of urethral balloon-dilating catheters. These catheters may be attached to a filiform tip or passed over a guidewire or may come with an integral coudé tip. For initial dilation, we favor the use of balloons placed over wires that have been passed through the stricture under endoscopic control.

Dilation can be curative and, in the literature, in correctly selected patients, has short-term and mid-term efficacy rates equal to internal urethrotomy. Selection criteria are discussed in the following section on internal urethrotomy. The literature does not compare internal urethrotomy and dilation in randomized selection, and we do not have a true comparison but rather comparison by retrospective analysis (Steenkamp et al, 1997).

Internal Urethrotomy

Internal urethrotomy refers to any procedure that opens the stricture by incising it transurethrally. The urethrotomy procedure involves incision through the scar to healthy tissue to allow the scar to expand (release of scar contracture) and the lumen to heal enlarged. The goal is for the resultant larger luminal caliber to be maintained after healing.

With epithelial apposition, wound healing occurs by primary intention. Internal urethrotomy does not provide an epithelial approximation but rather aims to separate the scarred epithelium so that healing occurs by secondary intention. In healing by secondary intention, epithelialization progresses from the wound edges. As it progresses from the wound edge, epithelialization slows. In an effort to aid epithelialization, nature invokes the forces of wound contraction, not to be confused with scar contraction. Wound contraction closes the wound defect and limits the size of the area that requires epithelialization, hastening the healing of the surface defect. However, in the case of internal urethrotomy, wound contraction merely tries to reapproximate the edges of the scar, putting a race into effect. If epithelialization progresses completely before wound contraction significantly narrows the lumen, the internal urethrotomy may be a success. If wound contraction significantly narrows the lumen before completion of epithelialization, the stricture has recurred. [Dubey and colleagues \(2005\)](#) showed the extent of luminal narrowing to be a predictor of success with internal urethrotomy: The narrower the percent of narrowing, the worse the outcome, with a cutoff of 74% narrowing.

Many surgeons have learned to perform internal urethrotomy by making a single incision at the 12 o'clock position. However, this location might be questioned on the basis of the location of the urethra within the corpus spongiosum. On examination of a cross section of the corpus spongiosum, it can be seen that the thinnest portion of the anterior aspect is from 10 o'clock to 2 o'clock. The distance between the anterior wall of the urethra and the corpora cavernosa is likewise short in the bulbous urethra, and a single incision at 12 o'clock could rapidly penetrate the corpus spongiosum and extend into the triangular ligament; although it might not enter the corpora cavernosa, a deep cut could enter the intracrusal space. Distally, although the anterior aspect of the corpus spongiosum is thicker, a deep incision in the more distal aspects of the anterior urethra would enter the corpora cavernosa, and these incisions have been associated with erectile dysfunction thought to be due to local cavernosal veno-occlusive dysfunction. Vigorous incisions at 10 o'clock and 2 o'clock in the bulbous urethra risk the same problem. If deep spongiofibrosis is present, stricture cure is

impossible by internal urethrotomy, and these deep incisions are unnecessary.

The most common complication of internal urethrotomy is recurrence of stricture. Less commonly noted complications of internal urethrotomy include bleeding (almost always associated with erections immediately after the procedure) and extravasation of irrigation fluid into the perispongiosal tissues. These complications are rare today because of the less frequent use of aggressive internal urethrotomy as a treatment modality for urethral strictures. Normal saline should be used as the irrigant when direct visual internal urethrotomy is performed. Additionally, with the use of deep urethrotomy incisions, another complication can be creation of a fistula between the corpus spongiosum and the corpora cavernosa and cavernosal veno-occlusive dysfunction.

A major problem with assessing the success rates of internal urethrotomy is that the nature of the strictures that have been treated with internal urethrotomy has been poorly reported. In addition, the literature is unclear regarding the goal of internal urethrotomy. For many, an internal urethrotomy is successful if it offers temporary relief. In many cases, internal urethrotomy has been reported as successful despite the fact that it has been associated with eventual stricture recurrence. A report by [Santucci and McAninch \(2001\)](#) using actuarial techniques showed the curative success rate of internal urethrotomy to be approximately 20% ([Rosen et al, 1994](#)). Evaluations by [Pansadoro and Emiliozzi \(1996\)](#) and others showed the curative success rate of direct visual internal urethrotomy to be approximately 30% to 35%. Their analysis also showed that there is virtually no increase in success rate with a second internal urethrotomy. **The data show that strictures at the bulbous urethra that are less than 1.5 cm in length and not associated with dense, deep spongiofibrosis (i.e., straddle injuries) can be managed with internal urethrotomy, with a 74% moderately long-term success rate.** The study by Pansadoro and Emiliozzi (1996) did not have any long-term successes for treated strictures outside the bulbous urethra. The variables associated with success of internal urethrotomy have been verified by other studies ([Heyns et al, 1998](#)). Many studies have shown that the success of reconstruction is diminished by multiple prior urethral dilations and internal urethrotomy ([Stone et al, 1983](#); [Albers et al, 1996](#); [Heyns et al, 1998](#)) ([Boccon-Gibod, personal communication, 2005](#)). Success rates with internal urethrotomy are not equal to success rates of open urethral reconstruction ([Mandhani et al, 2005](#)). Numerous analyses have sought to compare the cost-effectiveness of the practice of internal urethrotomy initially before consideration of open reconstruction. The analyses all differ in method and differ in findings ([Rourke and Jordan, 2005](#); [Wright et al, 2006](#); [Wessells, 2009](#)).

Several techniques have been employed to oppose the process of wound contraction and to prevent stricture recurrence. One method is to leave an indwelling Foley catheter for 6 weeks after urethrotomy, in the hope that the urethra will mold around the catheter as it heals. However, studies have shown that the failure rate of long-term catheterization after internal urethrotomy is similar to that seen with 3 to 7 days of catheterization, and even 6 weeks is insufficient time to oppose the forces of wound contraction.

Another technique used to oppose the forces of wound contraction after internal urethrotomy is home self-catheterization or home urethral obturation. After internal urethrotomy, patients generally have an indwelling catheter placed for 3 to 5 days. When the catheter is removed, the patient is started on a urethral obturation regimen. Most regimens require more frequent catheterizations early in the recovery period, with a tapering schedule during the next 3 to 6 months. Anecdotally, many surgeons have reported an improved cure rate with self-catheterization combined with internal urethrotomy. However, it has been our experience that the stricture inevitably recurs when the patient stops self-obturation, regardless of how long it has been used. That being understood, this approach can effectively manage the problems when it is combined with a urethral dilating regimen in a properly motivated patient. Colchicine, because it binds tubulin, has been used along with internal

urethrotomy (Carney et al, 2007). Initial findings in a nonrandomized study also suggest that, perhaps by pharmacologically blocking tubulin and possibly wound contracture, the results of internal urethrotomy may be better. Mitomycin C with its antifibroblast and anticollagen activity when injected submucosally has been shown to decrease the risk of recurrence after a urethrotomy (Mazdak et al, 2007).

Urethral stents (removable or permanently implantable) are another modality used in opposing the forces of wound contraction after internal urethrotomy or dilation. Removable urethral stents are designed to prevent the process of epithelialization from incorporating the stent into the urethral wall and are left in place for 6 months to 1 year before they are removed. The greatest experience with these removable stents comes from Israel (Yachia and Beyar, 1991), and centers there report good success in small series. The Memokath stent is not currently available in the United States. It is a removable stent made of nitinol with varying success rates.

Most experience with permanently implantable stents comes from Europe and the United Kingdom. Milroy (1993) reported a success rate of 84% at 4.5 years with use of the permanently implantable UroLume (Rousseau et al, 1987; Sigwart et al, 1987; Milroy et al, 1988, 1989; Sarramon et al, 1990; Ashken et al, 1991; Krah et al, 1992; Sneller and Bosch, 1992; Verhamme et al, 1993; Badlani et al, 1995; Milroy and Allen, 1996; Jordan, 1997; Tillem et al, 1997; Brandes and McAninch, 1998; Shah et al, 2003). The UroLume, made of an alloy, is designed to be incorporated into the wall of the urethra and corpus spongiosum. Available data show that the stent is best employed for relatively short strictures of the bulbous urethra associated with minimal spongiofibrosis. However, these are the strictures that are most successfully reconstructed with open techniques that offer better long-term success rates. The North American Study Group 11-year data showed that of 179 patients originally enrolled in the North American Study, 24 patients completed 11 years of follow-up. The overall success rate for all patients enrolled at 11 years is less than 30% (Shah et al, 2003). A 10-year follow-up study from The Netherlands (De Vocht et al, 2003) reported results thought to "weaken the optimistic early results"; of 15 patients implanted, only 2 were satisfied with their stent at 10 years.

Permanently implantable stents are associated with unique complications. The stents must be placed only in the bulbous urethra, and when placed beyond the area of the scrotal urethra, placement has been associated with pain on sitting and intercourse. Some patients (particularly young patients) complain of perineal pain, often with vigorous activity, even after implantation of the stent in the deep bulbous urethra. In addition, longer bulbous strictures require two stents that are overlapped. These stents can migrate away from each other, leaving a gap between them where recurrence of stricture is inevitable. When this occurs, the stricture recurrence is excised, and a third stent is placed to span the gap.

There are also specific contraindications to the use of the UroLume. Patients who have undergone prior substitution urethral reconstruction, particularly where skin has been incorporated into the urethra, have been shown to be poor candidates for implantation with the UroLume stent because contact of the stent with the skin is associated with a virulent hypertrophic reaction. These patients experience postvoid dribbling, and the hypertrophic reaction can be so severe in some cases that functional recurrence of the stricture results. Another subset of patients shown to be poor candidates for the UroLume includes patients with strictures associated with deep spongiofibrosis. Patients who fall into this category have had urethral distraction injuries and straddle injuries associated with deep fibrosis. UroLume has been taken off the market and is currently not available for implantation. However, there are still many patients who will present with UroLume stents, and many will need treatment.

To date, the results of laser urethrotomy are mixed. However, with the advent of new lasers and experience with them, future data may show better results.

Open Reconstruction: Excision and Reanastomosis

It has been demonstrated with certainty that the most dependable technique of anterior urethral reconstruction is the complete excision of the area of fibrosis, with a primary reanastomosis of the normal ends of the anterior urethra (Fig. 40-19) (Russell, 1914). The best results are achieved when the following technical points are observed: The area of fibrosis is totally excised; the urethral anastomosis is widely spatulated, creating a large ovoid anastomosis; and the anastomosis is tension free.

Figure 40-19. Techniques for excision and primary reanastomosis of anterior urethral stricture. A, The bulbospongiosus is released from its attachment to the perineal body. The arteries to the bulb are not divided. This technique allows the urethra to be mobilized distally. This technique combined with development of the intracru-ral space can shorten the path of the urethra by approximately 1 to 1.5 cm. B, Technique of a primary spatulated anastomosis after excision of an anterior urethral stricture. (From Jordan GH. Principles of plastic surgery. In: Droller MJ, editor. Surgical management of urologic disease: an anatomic approach. Philadelphia: Mosby; 1992. p. 1218–37.)

Lasers

Please see the Expert Consult website for this section.

Types of lasers that have been used for the treatment of urethral stricture disease include carbon dioxide (CO₂), argon, KTP, Nd:YAG, holmium:YAG, and excimer lasers. The ideal laser for use in the treatment of urethral stricture disease is one that totally vaporizes tissue, exhibits negligible peripheral tissue destruction, is not absorbed by water, and is easily propagated along a fiber. Although the CO₂ laser appears to be ideally suited, it must be used with a gas cystoscope, which carries the potential threat of a CO₂ embolus.

For the argon and the Nd:YAG lasers, the predominant mode of action is thermal necrosis, which leads to a significant potential for peripheral tissue injury rather than vaporization. The Nd:YAG laser has also been used with a bare fiber in the contact mode. A bare fiber carries with it a risk of forward scatter. When it is used in the contact mode, the YAG energy is transferred to a sapphire tip. Advocates of the use of a contact laser suggest that it obliterates the scar by vaporization; however, results with use

of these fibers are no better than results with direct cold-knife visual internal urethrotomy.

A KTP laser is essentially an Nd:YAG laser that has passed through a KTP crystal, resulting in a reduced depth of penetration. A KTP laser urethrotomy is accomplished by passing the fiber over the scar tissue to make urethrotomy cuts. The holmium:YAG laser has properties similar to the KTP laser, and, similar to the KTP laser, it provides direct contact cutting and vaporization with minimal forward scatter. Experience with the holmium:YAG laser is accumulating; anecdotally, it may have a place in the management of some strictures, in particular, strictures that are relatively isolated and short.

The excimer laser is a true vaporizing laser that has little forward scatter or peripheral tissue necrosis associated with it. Little experience with this laser has been reported, but future investigation is warranted.

The success of this procedure relies on vigorous mobilization of the corpus spongiosum. With vigorous mobilization, dissection of Buck fascia to improve compliance, development of the intracanal space, and detachment of the bulbospongiosus from the perineal body, significant lengths of stricture can be excised and reanastomosed. Strictures of 1 to 2 cm are generally easily excised with reanastomosis. In some cases, strictures 3 to 5 cm can be totally excised, and a primary reanastomosis of the anterior urethra can be performed. For very proximal short-length bulbous strictures, tension-free anastomosis can be facilitated by the dissection of the membranous urethra (Fig. 40-20). As a rule, the closer the stricture is to the membranous urethra, the longer it can be and still be reconstructed with anastomotic techniques. For many proximal strictures, a single-layer anastomosis is preferable. When the length of stricture precludes total excision of fibrosis with primary anastomosis, tissue transfer is required. Morey and Kizer (2006) published a series of patients who had stricture excision with anastomosis for strictures up to 5 cm and pointed out that younger patients have more compliant tissue, allowing the limits to be stretched.

DeCastro and associates (2002) reported an interesting variant of excision with anastomosis for anterior stricture. In that case report, a patient had two independent areas of stricture apparently separated by totally normal urethra and corpus spongiosum. The authors excised both areas of stricture independently with respective anastomosis of each site. Although this case was successful, we think that the authors' considerable experience allowed them to achieve a successful result, and a safer reconstruction with use of onlay or augmented onlay might have been better.

Jordan and colleagues (2007) first reported the use of a vessel-sparing excision and reanastomosis of the bulbar urethra. The dissection is similar to the standard excision and reanastomosis

(Fig. 40-21): The triangular ligament is divided, and the intracanal space is developed, the space between the membranous urethra and the proximal vasculature is developed, and these vessels are preserved (Fig. 40-22). The urethra is divided with the stenotic segment excised, the ends are spatulated, and the reanastomosis is performed. Andrich and Mundy (2012) described an alternative vessel-sparing technique for proximal strictures in which a longitudinal dorsal stricturotomy is performed and the stricture is excised from within the urethra without disrupting the spongiosum. After stricture excision, the ventral urethra is reapproximated primarily, and the longitudinal dorsal stricturotomy is closed horizontally, preserving the vasculature. Preserving the proximal blood supply to the bulbar urethra is advantageous in patients whose distal blood supply is compromised by trauma, previous surgery, or hypospadias. Another theoretical advantage would be a decrease in the risk of erectile dysfunction and potential decreased risk for erosion if subsequent artificial sphincter implantation were probable. Further studies need to be done to confirm the initial excellent results with the vessel-sparing technique and prove the theoretical advantages (Jordan, et al 2007; Gur and Jordan, 2008; Andrich and Mundy, 2012).

Four grafts that have been successfully used for primary urethral reconstruction are the full-thickness skin graft, bladder epithelial graft, oral mucosal graft, and rectal mucosal graft. Oral mucosal grafts, as mentioned earlier, can be taken from the cheek (buccal), the lip (labial), and the undersurface of the tongue (lingual). Split-thickness skin grafts have been used for staged anterior urethral reconstruction (Humby, 1941; Memmelaar, 1947; Pressman and Greenfield, 1953; Devine et al, 1976; Hendren and Crooks, 1980; Schreiter and Koncz, 1983; Webster et al, 1984; Hendren and Reda, 1986; Ransley et al, 1987; Burger et al, 1992; Jordan, 1993; El-Kassaby et al, 1996; Wessels and McAninch, 1996). The characteristics and microvasculature of some

Figure 40-20. Technique of excision of very proximal bulbous urethral stricture with reanastomosis. This technique is facilitated by dissection of the membranous urethra. A, The area of the stricture is defined for excision. B, The stricture is excised, and both ends of the urethra are spatulated on the dorsal aspect. C, The anastomosis is complete.

Figure 40-21. Diagrammatic representation of the dissection of the proximal corpus spongiosum, bulbospongiosum, and membranous urethra. The customary technique for dividing the urethra through the juncture of the membranous urethra with the proximal bulbous urethra—to perform an excision of stricture with a primary anastomosis. In this illustration, the proximal vasculature has been ligated and divided. The urethra can then be divided at the distal-most limits of the membranous urethra.

Figure 40-22. Technique of vessel-sparing excision with primary anastomosis. The proximal corpus spongiosum, bulbospongiosum, and area of the proximal vessels and membranous urethra have been dissected. **A**, Dissection of the space between the proximal vasculature and the membranous urethra is illustrated. In this technique, the arteries to the bulb can be preserved, and the membranous urethra can be divided at its juncture with the bulbous urethra. The area of proximal stricture can be excised. **B**, The stricture has been excised before placement of the anastomotic sutures. **C**, Anastomotic sutures are placed to effect the spatulated anastomosis. At this center, customarily we alternate polydioxanone sutures with Monocryl; however, any acceptable absorbable suture can be used. The membranous urethra is spatulated on the dorsum as is the proximal bulbous urethra.

Figure 40-23. Various techniques of graft onlay. **A**, Ventral onlay with spongioplasty. **B**, Lateral onlay with quilting to the ischiocavernosus muscle. **C**, Dorsal onlay with spread fixation of the graft.

of the grafts were discussed earlier in Principles of Reconstructive Surgery.

Graft reconstruction of the urethra was almost abandoned in favor of flap reconstruction techniques. However, since the late 1990s, there has been a resurgence of interest in the use of grafts (Wessells and McAninch, 1996) and, specifically, the use of buccal mucosal grafts (Hellstrom et al, 1996; Weinberg et al, 2002; Barbagli et al, 2003; Elliott et al, 2003; Bhargava and Chapple, 2004; Kellner et al, 2004; Xu et al, 2004; Dubey et al, 2005). Grafts have been employed most successfully in the area of the bulbous urethra, where the urethra is invested by the bulk of the ischio-cavernosus muscles. However, the use of grafts other than in the area of the bulbous urethra and, in some cases, the use of tubed reconstruction are reported in increasing numbers. The grafts can be applied to the ventrum of the urethra; however, a ventral urethrotomy seems to be advantageous only if use of the spongioplasty maneuver is contemplated (Fig. 40-23). The spongioplasty procedure requires that the corpus spongiosum adjacent to the area of the stricture be relatively normal and free of fibrosis. There are data to support the superiority of results with the dorsal onlay technique and other reports showing no difference in success.

In the past, we preferred to use lateral graft onlay (see Fig. 40-23B) or dorsal graft onlay (see Fig. 40-23C). Placement of the urethrostomy laterally allows exposure of the urethra while cutting through the corpus spongiosum, where it is relatively thinner, limiting bleeding and maximizing exposure. In addition, in the bulbous urethra, the graft can be sutured to the underlying muscle bed in the hope of improving graft–host bed immobilization and approximation.

The Monseur urethral reconstruction was applied in only a few select centers (Monseur, 1980). In this technique, the urethrostomy was made through the stricture on the dorsal wall. The edges of the stricture were sutured open to the underlying triangular ligament or corpora cavernosa, or both. Barbagli and associates (1995) subsequently modified the Monseur technique (Fig. 40-24). In their modification, the urethrostomy is performed through the stricture on the dorsal wall. In the area of the urethrostomy, a graft is applied and spread fixed to the triangular ligament or corpora cavernosa, or to both. The edges of the stricturotomy are sutured to the edges of the graft and to the adjacent structures. The results of this technique are excellent. The ventral and dorsal graft onlay techniques can be used with stricture excision and strip anastomosis (augmented
